A THEORETICAL  
AND  
PRACTICAL TREATISE  
ON THE  
DISEASES OF THE SKIN,

BY  
P. RAYER, M.D.,

PHYSICIAN TO LA CHARITÉ HOSPITAL, MEMBER OF THE ROYAL ACADEMY OF MEDICINE, CONSULTING PHYSICIAN TO THE KING, &c., &c.

FROM THE SECOND EDITION, ENTIRELY REMODELLED.

WITH NOTES AND OTHER ADDITIONS,

BY  
JOHN BELL, M.D.,

FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA; MEMBER OF THE AMERICAN PHILOSOPHICAL SOCIETY, AND OF THE GEORGIFILI SOCIETY OF FLORENCE.  
AND JOINT AUTHOR OF "BELL AND STOKES'S LECTURES ON THE THEORY AND PRACTICE OF PHYSIC."

With Forty Beautifully Coloured Plates,

CONTAINING FOUR HUNDRED SEPARATE ILLUSTRATIONS,  
CAREFULLY COLOURED FROM NATURE.

PHILADELPHIA:  
CAREY AND HART, 126 CHESTNUT STREET,  
FOR G. N. LOOMIS.  
1845.

REGISTERED

DECEMBER 1, 1845

WILLIAM HART

---

IN this new edition, as in the first, the Diseases of the Skin are classed according to their general pathological characters, and the orders are established on the basis of the method pursued by Willan. Several changes have been made in the distribution of that part of the work which treats of the malformations and alterations in the structure of the skin, of the diseases of the follicles, and of those of the nails and hair.

I have recast the whole of the descriptions, and endeavoured to make them more accurate and more complete than they were before. I have added considerably to the therapeutical considerations, as well by reverting to the facts and cases published before the first edition of this work appeared, as by taking note of all with which science has since been enriched. I have not confined myself to pointing out the therapeutical means whose effects were familiar to me in consequence of having tested them myself, but have signalized a variety of other remedies which have been recommended by different practitioners.

Important additions have been made to the history of several diseases, particularly that of the variolous and vaccinal eruptions, of scabies, of the syphilides or cutaneous eruptions consequent on a venereal taint of the system, of purpura, lupus, cutaneous scrofula, and the inflammations of the skin excited by artificial or accidental means generally. I have also given a more ample account of those diseases of the skin which are peculiar to different countries, and of several diseases of the lower animals susceptible of transmission to the human species.

In a brief historical notice I have referred to the earliest observations extant on each disease discussed, to the series of inquiries which successively rendered its history more complete, and to the best monographies in which these various accounts have been collected, and their sum and substance exhibited in connection.

To conclude, I have thought it well, in a practical work, to support and illustrate general principles by a constant reference to particular instances, which should exhibit the individualities as it were, of the different forms of cutaneous diseases, which should show the application of the various therapeutical measures recommended, or which should make the reader acquainted with forms not yet described, or with rare complications, that could hardly have found a place in a general description: with this view, I have selected and given the details of two hundred cases of every interesting form and variety of affection of the skin, the whole of which were written under my own eye by the pupils successively attached to me as physician to the Hôpital Saint Antoine and the Hôpital de la Charité.

*Paris, March the 8th, 1835.*

---

### NOTE BY THE TRANSLATOR.

This English Edition is in all respects similar to the French one. Very little room was found for addition of any kind, and to have retrenched from the text, would have been to do the author injustice. The work is therefore given complete, and little beyond an explanation of the various therapeutical means and formulæ recommended is added in foot notes. The sense of one passage only has been intentionally changed; this stands at the bottom of page 177, and in the original gives us to know that the Eliaats, a nomadic Asiatic tribe, had from time immemorial been in the habit of *inoculating cow-pox, with a view to prevent the attacks of small-pox*,—the suggestion which has made the name of Edward Jenner immortal. The startling assertion, however, comes from the author having misquoted a passage from the Bombay Transactions. On referring to the original, it was found stated that the Eliaats were familiar with *the preservative powers of cow-pox against small-pox*, just as the peasantry of Gloucestershire were. The reading is consequently restored to its proper signification.

R. WILLIS, M.D.

THE HISTORY OF THE

REIGN OF KING CHARLES THE FIRST

IN WHICH ARE CONTAINED THE  
MOST IMPORTANT PASSES OF HIS  
MILITARY AND POLITICAL LIFE  
FROM HIS FIRST ASCENSION TO THE  
THRONE TO HIS DEATH  
BY JOHN BURNET  
OF THE SOCIETY OF THE APOSTOLICAL APOSTLES  
IN THE NINETEENTH CENTURY

## TO THE AMERICAN EDITION.

---

THE magnitude and copiousness of the great work of M. Rayer on Diseases of the Skin, while precluding the hope of successful rivalry on this side of the Atlantic, would seem, for these very considerations, to render the task of addition and comment comparatively light and easy, and to exonerate him from the charge of presumption who might be persuaded to perform this humble duty. Whether well founded or not, it was under such a belief that the Editor was induced to accede to the wish of the publishers, that he would superintend this first American edition.

Although it so happens, that his contributions have been much more various and extensive than he had at first contemplated, the Editor has constantly endeavoured to adhere closely to the course pursued by the distinguished author himself; in his giving a preference for the practical over the speculative, and in illustrating general principles by particular cases. Free use has been made of the works of Plumbe and Mr. E. Wilson; the more rightfully, as their pages are continually enriched by the observations derived from M. Rayer's volume. Contemporary French authors have not been overlooked; but to the pages of the different Medical Journals, which contain so much valuable matter on the pathology and treatment of many cutaneous diseases, is the Editor under the greatest obligations. From these sources are derived many of his chief additions, as, for example, on variola, vaccinia, syphilida, molluscum and glanders.

The notes of the translator, Dr. Willis, have been retained: they are in small type and accompanied with the initials, R. W. The contributions of the American Editor in the same type with that of the text, are given at the foot of the page, and are always indicated by the letter (*a*) or (*b*), &c. prefixed. In one instance alone, "Outlines of the Pathology and Remedial Treatment of Diseases of the Skin," he has introduced his observations into the body of the work.

The Editor was fain to avail himself of the option kindly allowed him by the publishers, to undertake or decline, as he might deem convenient, the supervision of the engraving and colouring of the plates which give so much interest and value to the present work, and which will constitute, in the eyes of many, its most attractive feature. His existing engagements not allowing him to execute this duty in a manner satisfactory to himself, the services of Dr. Goddard were enlisted by the publishers for the purpose. On him, also, devolved the translation of the letter-press explanations that accompany the plates. The result is such as might have been expected from the well known artistical taste and practised eye of this gentleman; and it is believed, that the coloured engravings in the American edition, which are of the same number and size as in the French and English editions, will bear a scrutinizing comparison with these latter in their style and finish of execution, and exhibit in favourable relief the merits of the Philadelphia artists engaged in the work.

# INTRODUCTION.

It is long since the study and description of those diseases which appear on the exterior of the body with characteristic symptoms, were detached from general pathology; and it is impossible to deny that the history of these diseases has been more fully and satisfactorily given by the writers who have made them objects of their peculiar consideration. Nevertheless, it must be allowed, that many serious inconveniences would arise from completely abstracting this study from that of the other morbid conditions of the economy. It would, above all, be a grave error to separate certain cutaneous eruptions from lesions of other systems, when both derive their origin from the same cause: to attempt to isolate the venereal eruptions, for example, from the other symptoms of syphilitic infection—exostoses, periostoses, nocturnal pains in the bones and joints, &c., would evidently be arbitrarily to disconnect the different orders of symptoms of one and the same disease. These venereal eruptions have farther so intimate a relationship with the primary symptoms to which they generally succeed, that it even becomes imperative on us to include both under the same general head of investigation.

Certain diseases, such as the *eruptive fevers*, produced by infection of the whole system, although they indeed exhibit themselves on the exterior of the body at determinate periods in peculiar and characteristic symptoms, are, to all intents and purposes, *general diseases*, the effects of which are occasionally felt with far greater violence by other systems, than by the skin. In some cases, indeed, in variola, rubeola, scarlatina, &c., no eruption ever makes its appearance, and the skin then continues entirely a stranger to the effects of the contagion. Who does not know, moreover, that these diseases impress or modify the constitution so deeply, that it generally becomes forever after unsusceptible of being influenced, by the cause which produces them?

In some diseases which are entitled cutaneous, the affection of the skin, so important in a diagnostic point of view when it occurs, is so completely secondary in the question of their nature, that this alteration, which sometimes only shows itself at an advanced stage of the disease, may disappear when the general symptoms acquire greater intensity, and only reappear when these decline; the severity, like the nature of the disease, being linked to morbid conditions of the economy other than those of the skin, as is abundantly evident in purpura, measles, &c.

If in the eruptive fevers and the syphilides, the evidences of a general constitutional affection appear in a multitude of phenomena, the connection of several other alterations of the skin with a particular state of the constitution is no less evident; it is very striking in scrofulous tubercles and ulcers, which are always preceded or accompanied with other symptoms of a strumous nature.

Besides these cases of general infection, and of original or hereditary disposition of the constitution, which are transmitted to the skin, or manifest themselves there in the shape of eruptions of divers forms, the principal phenomena of several morbid states of the system at large, and of certain derangements of important organs, are peculiar affections of the skin. Erysipelas is occasionally seen supervening periodically, every month, or every two months, at the usual menstrual periods, when the catamenia fail or are deficient in quantity; strophulus is one of the most usual morbid phenomena at the time of teeth-

ing; urticaria and lichen *urticatus* frequently succeed derangement of the digestive functions, &c. Outward symptoms of complex morbid states, these eruptions then possess characters very distinct from those that are proper to them, when they arise under other circumstances.

There are very many cases in which, without being able to demonstrate such a thing rigorously, the existence of a connection of the above kind, or of certain relations of various affections of the skin with particular states of the constitution, cannot be called in question. Who is not aware that many of the diseases generally designated as *tettery* in their nature, or as *scall*, such as eczema, lichen, psoriasis, &c., are frequently hereditary, and that they occur among individuals of the same family, even when placed in very different social positions? A point that is not less incontestable is, that it is impossible in an immense number of cases, to ascribe to any outward cause the development or spontaneous disappearance of a great variety of *herpetic* affections; and, when the slowness of their progress, and the frequency of their recurrence, are contrasted with the facility and the promptitude with which artificial or accidental eruptions of almost all kinds are cured, we are naturally led to conclude, that the former are dependent upon peculiar states of the constitution, states which several authors and the vulgar have designated collectively under the title of *tettery*, *scorbutic*, &c.

We should even have a very imperfect notion of the variable nature of certain cutaneous affections, did we not take note of their relations in the chain of cause and effect with a variety of other diseases. There is so intimate a connection betwixt gout and gravel, that the gouty are frequently liable to alternate attacks of these two affections, and when one of them has influenced the constitution deeply, the other is often long of showing itself. Without being either so constant or so striking, alternate attacks of gout, lichen, *agrius*, chronic eczema and psoriasis are still so frequently observed in the upper walks of life, that there does actually appear in some cases to be a kind of consanguinity between these affections despite of the dissimilarity of their appearances.

On the other hand, there is always this wide difference between the diseases, which, to make use of an old expression, *have their roots in the interior*, and the eruptions produced by the action of external stimulants upon the skin, which I have denominated *artificial eruptions*, even when both appear with the same elementary forms, that they always belong to two distinct orders of diseases.

Not only is the nature of the several affections of the skin independent of their external appearances, but every circumstance in these diseases, their beneficial or noxious influence upon the system, their amenableness or rebelliousness to curative means, all, even to their very nature, is modified by different states of the general system,—by the influence of age, the tear and wear of the constitution, &c. The impetiginous eczema of infants, *crusta lactea*, was long ago recognized as an affection which was frequently beneficial rather than injurious to the general health, and one which got well spontaneously, after the lapse of a certain time, without the necessity of having recourse to remedial measures of any kind. Who, on the contrary, is not aware of the fact when an eruption of this kind makes its appearance about the age of puberty, and when the menstrual function is irregular, that cures obtained by every means, often by the use of

agents of the most active description, are frequently followed by speedy relapses, and that recovery is never either complete or attended with beneficial effects, so long as a function of so much consequence in the female economy remains deranged? Almost all the eruptions that appear about the critical age, it matters not what their form may be, are extremely rebellious; considered in the light of supplementary excretions, as they are by some pathologists, or as critical and eliminatory discharges by others, it is always difficult, and occasionally dangerous, to attempt to cure them. The more we study the development and tendency of the greater number of the diseases of the skin which invade independently of any outward appreciable cause, the more we become convinced of their connection with the state of the constitution, and of the necessity there is for considering them under this point of view before we think of undertaking their cure, or even of interfering with them so as to modify their progress.

The field of observation, and the difficulties that surround it, increase in extent and magnitude in relation to the acute diseases upon which certain epidemic constitutions impress a character of mildness or of malignity that proves a remarkable feature, and gives a similarity to the whole of the individual cases; this has been particularly observed in almost all the epidemic variolas, scarlatinas, &c., that have ever prevailed. The principles of prognosis and treatment in such emergencies are rather to be sought for in the histories of analogous epidemics, than in the general descriptions we possess of the disease occurring under ordinary circumstances. In the same way we know that at certain seasons, and during certain medical constitutions the character of an eruptive fever is occasionally so uniform, that the same mode of treatment proves applicable in the plurality of the cases encountered, without much regard being paid to individual peculiarities or conditions. The influence of seasons and prevailing medical constitutions, however, is much less evident than that of epidemic constitutions.

A small number of diseases—cancer and melanosis particularly, when they appear upon the skin, are most commonly the outward manifestation of a diathesis, the effects of which either are already, or speedily will be, felt by one or other of the internal organs; it very rarely happens that the action of these diseases is limited to the point or points of the skin upon which they seem to fasten themselves.

Certain affections of the skin, such as eczema and lichen, are occasionally seen to occur in the course of an internal malady, and their evolution to be followed by a favourable solution of the disease. On the other hand, it is by no means unfrequent to observe the more or less complete disappearance of a variety of cutaneous eruptions, not only on the invasion or during the course of an acute disease, but also on the attack and at any period in the continuance of a chronic affection of an internal organ. It is more particularly between the diseases of the mucous membranes and those of the skin that these *melastases* are observed, which prove prejudicial or salutary, according as the disease is diverted to the interior or exterior of the body. In any case in which these alterations have been observed, the affection of the skin once apparent must not be meddled with; the object of the practitioner must rather be to fix it, to bring it back, in the event of its having disappeared, and afterwards to favour its evolution, in the hope of ultimately guiding it to a fortunate issue.

In a word, every day's observation proves more and more satisfactorily, that the study of the diseases of the skin cannot be detached from that of general pathology, and of the multifarious morbid conditions with which they have such numerous and varied relations. A knowledge of these diseases, in fact, implies familiarity with general infections, hereditary predispositions, the effects of regimen, mode of life, &c.: it concludes acquaintance with the maladies which have preceded them, knowledge of the internal lesions which accompany them, appreciation of the organic changes which follow certain eruptions, prescience of the affections which are apt to supervene on their disappearance, &c. That such general views may acquire practical value, however, that they may be advantageously applied to the treatment of the diseases of the skin, the extent of these relations and influences, striking in some cases, contested or altogether inappreciable in others, requires to be studied and estimated, as much as may be, in the *species* severally and even in the morbid individualities of each

particular case, the whole of the circumstances and every one of the elements being taken into account.

Hippocrates<sup>1</sup> remarked that the same eruptions occurred under two different aspects, according as they existed by themselves, or as they were the *depositories of a morbid state* (ἀποστασεις)<sup>2</sup>. These solutions of disease by the skin<sup>3</sup> he says, are announced by tubercles, tumours, pustules, ulcers, alopecia, &c., in proportion to the rapidity of the development of which is that of the solution itself in any given case. When the solution of the disease does not happen by the formation of tubercles, or ulcers of the skin, or in some other evident way, relapses are frequent and follow rapidly. This relation between cutaneous eruptions and diseases generally, is mentioned in several other passages, in which the father of physic appears rather to enquire into the *significance* of these eruptions, than to describe or study them in themselves.<sup>4</sup> Yet he does consider them elsewhere, under other points of view, namely, those of their nature and treatment,<sup>5</sup> their relations with different ages,<sup>6</sup> and even with the seasons.<sup>7</sup> The strumous affections of childhood, the eruptions that accompany teething, the occurrence of cancer among individuals of mature years, and of prurigo among the aged, had all attracted his observation.

Hippocrates describes erysipelas, and the ill consequences of its retrocession;<sup>8</sup> he mentions phlyctenæ and a great many eruptions, the names of which are still preserved in our medical nomenclature, such as eczema, ethyma, phlyzacia, psudracia; he makes several remarks on the summer hydræa, lepra, psoriasis, lichen, pityriasis,<sup>9</sup> on the pruriginous excoriations of the pudenda,<sup>10</sup> on the varieties of ephelis and their treatment;<sup>11</sup> he describes cancer;<sup>12</sup> he distinguishes different kinds of ulcers;<sup>13</sup> he mentions certain serious gangrenous

<sup>1</sup> Hippocratis Opera, interprete Foësius, in fol. Francfurti, 1621.—*Œconomia Hippocratis*, autore Foësius, in fol. Francfurti, 1588.—I have referred to this edition throughout, it being esteemed one of the most correct. I must remark, however, that in the translation of Foësius, as in all the others, into the Latin tongue, there are many expressions in the nomenclature rendered by words which, in the present day, have a very different signification; lichen, for instance, is translated *impetigo*, *exanthemata* is *pustulæ*, *alpos* is *vitiligo*, &c. To prevent any mistake from this cause, I have frequently placed the Greek word behind the Latin title of the translator.

<sup>2</sup> Impetigines (λεγχῖνες) et lepræ, albicantesque vitilignes (καὶ λευκαὶ) si juvenibus quidem aut pueris horum aliquid contingat aut, sensim se prodens, diuturnitate temporis augetur; in iis quidem, ex pustulæ abscessus esse minime existimandæ sunt, sed morbi. A quibus ex his aliquid subito multumque contingit, id certi abscessus (ἀποστασεις) dici possit. Oriuntur autem albicantes vitilignes ex maximè quidem lethali morbis, velet quæ morbus phæniceus (φαινικῆν) dicitur. Lepræ vero et impetigines ex iis qui ab atrabile fiunt. (Hippocratis Op. *Prædictorum*, lib. ii. p. 114.)

<sup>3</sup> Quinelliam quæ in cutem abscedunt, foras erumpentia tubercula (φύματα): velut putrescentes et purulenti quidam tumores, aut ulcus, aut reliquæ hujusce generis in cute efflorescentes pustulæ (ἐξανθήματα) desquamato, glabrato et capillorum defluvio, vitilignes (ἀλφῖς) scabies (λεπταὶ) alique hujusce modi, quæ, conferto et repentinò quodam confufluxu, non autem dimidiato, et semi repente abscedunt et quæcumque alia dicta sunt, etsi non indigne morbi excretionem respondeant. (Hippocratis, *De morb. vulgaribus*, lib. ii. p. 1002.)

<sup>4</sup> Quæ erumpere et febres decernere nata sunt ulcera ac tubercula, si non affuerint judicationem ipsam tollunt. Quibus vero intro subsistunt certissimas et celerissimas morborum recidivas afferunt. (De morb. vulgaribus, lib. ii. p. 1009.)—Lepra, prurigo, scabies (ψώρα), impetigines (λεγχῖνες), vitiligo (ἀλφῖς), et alopecia ex pituita oriuntur. Sunt autem ista fæditas potius quam morbi; favus (κνήσιν), struma; phygethia, furunculi et carbunculus, ex pituita oriuntur (De affectionibus, p. 525).—Quibus per febres assiduas pustulæ (φλύζα) toto corpore enascuntur, lethale est nisi quid purulentum abscedat. In his verò præcipuò adnasci ad aures tubercula solent (Coacæ prænotiones, p. 133).—Quibus ad articulos prærubræ pustulæ superficiales enatæ sunt, ac subinde rigent iis, velut ex acceptis plagis cum dolore venter et inguina rubescunt, et pereunt (Coacæ prænot., p. 195).—Pustularum eruptiones (ἐξανθήματα) velut summa cute leviter lacerata aut vellicata, totius habitus tabem et corruptionem denuntiant (Coacæ prænot., p. 189).—Eos (dolores) juvari spes est, si abscessus aliquis eruperit, aut pustulæ toto corpore pullularint. (Prædictorum, lib. ii. p. 109.)

<sup>5</sup> Cum fauces ægrotant, aut tubercula in corpore exoriuntur, excretiones in considerationem adhibendæ. Si namque biliosæ sint, corpus simul ægrotat. At si saniorum similes exiierint, secure corpus nutrias. (Aphorism., sect. ii.—aph. 15. sec. vii. lib. ii. p. 1244.)

<sup>6</sup> Prædictorum, lib. ii. p. 95.—Aphorism., sect. iii. aph. 31.

<sup>7</sup> Vere, lepræ, impetigines, vitilignes et pustulæ ulcerosæ plurimæ, et tubercula, et articulorum dolores (Aphorismi, lib. iii. sect. vii.—aph. sect. iii. aph. 20, p. 1243.)—Estate, et oris exulcerationes, genit alium putredines et sudamina. (Aph. sect. iii. aph. 21, p. 1243.)—Hyeme, viris—Pustulæ multæ nocturnæ, epinyctides dictæ. (De acre, locis et aquis, p. 281.)

<sup>8</sup> Prædictorum, lib. ii. p. 45.—Aphorismi, sect. vi. aph. 25.

<sup>9</sup> Prædictorum, lib. ii. p. 109.

<sup>10</sup> Si ulcera in pudendis innascantur, et pruritus corripial, oleæ, hederæ, rubi, et mali punici dulcis folia irita, vino veteri macerato, deinde carnem recentem foliis obduciam in subditio opposito, et per noctem teneat. (De nat. muliebri, 582.)

<sup>11</sup> De morbis mulierum, lib. ii. p. 667.

<sup>12</sup> De morbis mulierum, lib. ii. p. 648.

<sup>13</sup> At verò ulcera quatuor progrediendi modos mihi habere videntur. Unum quidem in profundum, cujusmodi sunt fistulosa, cicatrice obducta, et intus cava. Alterum quo

affections under the title of *Nomæ*,<sup>1</sup> lastly, he speaks of an epidemic fever<sup>2</sup> in which an eruption (*ἀθραξες*) similar to that produced by burns, was observed, a disease which has been regarded as small-pox by some commentators, and with more reason by others as a *bullous fever*.

Several particular cases in the Hippocratic collection, are remarkable either from inculcating the doctrine of *desposits* (*ἀπόσπασις*) or from the vigour and variety of the descriptions; such is the case of a wet nurse, the whole of whose body became covered with *ecthymata* when she gave over nursing;<sup>3</sup> such is that of Silene, labouring under severe fever, whose body became covered on the eighth day with *red spots*, and who died on the eleventh;<sup>4</sup> such is that of Thasus, who was attacked with a gangrenous affection of the foot, &c.<sup>5</sup>

Celsus<sup>6</sup> does not, like Hippocrates, study the cutaneous eruptions with reference to their origin and the crises they consummate. He remarks, however, that phlegmon sometimes appears after fever, that certain eruptions occur during the spring and summer seasons, and that others are most frequent among children, but he dwells little upon these relations. On the other hand, the ideas he conveys to us of these diseases are in general much more complete than those of Hippocrates; his description of furunculus, and hordeolum, of the callous ulcer, of chilblains, of erysipelas, especially the gangrenous species of the disease, of circumscribed lichen (first species of *papulæ*), of lichen *agryus* (second species of *papulæ*), of sycosis, psoriasis (third species of *impetigo*), of psoriasis *guttata*, and especially of Greek elephantiasis, cancer, malignant pustule (*carbunculus*), and a variety of diseases of the organs of generation and of the matrices of the nails, are not only remarkable for their accuracy, but farther for the excellent therapeutical precepts with which they are conjoined. Celsus farther describes various kinds of alopecia (*area ophiasis*) and sundry diseases of the hairy scalp (porrigo, cerion); it is more difficult to fix upon the precise diseases he mentions under the name of *ignis sacer*, *epinyctis*, *scabies*, *impetigo* of different kinds, &c.

Pliny<sup>7</sup> describes no disease particularly, but he mentions a host of simple and compound medicines for the cure of all that were known, those of the skin among the number. His nomenclature is the same as that of the Greek physicians. He gives the names of several eruptions of which Celsus makes no mention, of the lichen of children, of the prurigo of the aged, of prurigo *puerili*, of *furfures faciei*, &c. He also names several diseases which were new, or confined to certain countries, the contagious mentagra, and the gemursa of Italy, the carbunculus (anthracion) peculiar to Gallia Narbonnensis, and elephantiasis very common in Egypt. This writer also makes mention of several very active medicines against diseases of the skin, such as cantharides and elaterium internally, as well as the external use of vinegar, lime and alum. He even speaks of baths of the mineral waters, as often employed successfully in the treatment of ulcers and several other affections of the skin. (De differentia aquarum, medicinis, et observationibus.)

Galen<sup>8</sup> gives the details of several cases of herpes and elephantiasis; he has a long list of remedies against erysipelas, lichen, varus,

ad superiora tendunt, velutque super excrescentem carnem habent. Tertium in latum, qualia quæ serpentina dicunt. Quartus modus est, qui solus secundum naturam motus videtur. (De medico liber, p. 21.)—(De ulceribus, p. 869.)

<sup>1</sup> Nomæ verò maximæ sunt lethales, quæ putredines altissimè descendentes habent, suntque nigerrimæ et siccissimæ. Vitiosæ quoque et in periculum præcipitant, quæ saniem nigram reddunt. (Prædictor, lib. ii. p. 98.)

<sup>2</sup> Cranone carbunculi ætate grassabantur. Per magnos æstus affatim et continenter compluit, idque ab Austro magis. Sanies quidem plurima cuti subnascebatur, quæ intro conclusa dum incalesceret, pruriginem excitabat. Deinde verò in pustulas erumpebat iis affines, quæ in ambustis fieri solent. Tantus inerat sub cute ardoris sensus, ut uri viderentur. (De morb. vulg., lib. ii. p. 994.)

Aristophontis filiam febris tertio et quinto die prehendit, sicca plurimum permansit, alvus tamen huic conturbata est, difficilis judicatio fuit, supra triginta dies cessavit. Pustulæ, (*φλύκταιναι*) quidem ex laboribus non vehementibus, ad diem septimam perveniunt, aliquantulum lividæ (De morb. vulg., lib. iv. p. 1329.)

<sup>3</sup> Lactanti pustulæ (*ἐκθύματα*) per totum corpus eruperunt, quæ ad ætatem conserderunt, ubi lactare desiisset (De morb. vulg., lib. ii. p. 1013.)

<sup>4</sup> Octavo sudor frigidus per omnia membra diffusus est, cum pustulis (*ἐξanthύματα*) rubentibus, rotundis, parvis, varis non absimilibus, quæ permanebant neque abscesum faciebant (De morb. vulg., lib. i. p. 970.)

<sup>5</sup> De morb. vulg., p. 985.

<sup>6</sup> Celsus. De re medica. Ed. Fouquier et Ratier, 12mo. Paris, 1823.

<sup>7</sup> Plinii secundii. Historiæ mundi, lib. xxxvii. Venet. 1569.

<sup>8</sup> Galeni Opera, folio. Basilæ, 1562.—Novus index in omnia quæ extant Galeni opera. fol. Basilæ, 1562.

sycosis, &c.<sup>9</sup> But his theory of the humours constantly renders his descriptions obscure, and leads him away into numerous digressions. defects which the precision and purity of the painting of Celsus render still more striking. Although he studied sweating and the other critical phenomena particularly, and observes that ulcers of the skin are frequently an indication of a bad state of the constitution,<sup>10</sup> Galen does not insist to the same extent as Hippocrates, on the relation between cutaneous eruptions, and the solutions and the *ἀπόσπασις* of diseases.

The distinction of the cutaneous diseases into those which attack the *skin of the whole body*, and those which are confined to the *head* or to a few regions, is expressly mentioned by Galen in his *Isagoge*,<sup>11</sup> where he also notices the connection of several of these affections with gout and rheumatism. Under the title of *ἀχῆρ* and of *πυρίον* (*favus* of the Latin writers)<sup>12</sup> he clearly indicates the *humid eczema* of the scalp (*tinea mucosa*), and acute impetigo of the same part (*porrigo favosa* Willan).

Cælius Aurelianus<sup>13</sup> has left a number of details on the treatment of phthiriasis and elephantiasis, of which Aretæus presents us with a picture that is both more complete and more animated.<sup>14</sup>

Ætius<sup>15</sup> treats of several diseases of the skin after Archigenes, and of the affections of the genital parts after Leonidas. He describes with particular care a number of diseases of the skin, to which infants at the breast are liable, and he gives good precepts in regard to milk diet, on the use of baths, on that of cold water, on ablation in fever, and a great variety of other therapeutic means. Scribonius Largus<sup>16</sup> gives the characters of *zona*, which had already been mentioned by Pliny.

Alexander Trallianus<sup>17</sup> merely repeats the observations of the Greek medical writers, on the external diseases of the head.

Paulus Ægineta distinguishes lepra from psoriasis, and gives an excellent description of onychia maligna, under the name of *pterygion*. He recommends us not to interfere with the eruptions of infancy save in their decline, and dwells upon the influence of regimen, and of the milk of the nurse.<sup>18</sup>

The Arabian writers<sup>19</sup> have not only reproduced the observations of Hippocrates, Galen, Rufus Ephesius, Oribasius, Paulus Ægineta, &c., on the diseases of the skin, but were the first who described variola, rubeola and the elephantiasis, since entitled from them, *of the Arabians*. Avicenna<sup>20</sup> has given a particularly good account of anthracion and

<sup>9</sup> Galeni Opera, u.s. De compositione pharmacorum, secundum locos. Cl. v. p. 323.

<sup>10</sup> Magna tamen ex parte cutis, quoniam in hanc excrementa, quæ in habitum corporis colliguntur, natura expellit, multis et assiduus ulceribus afficitur quippe cancri, phagedænæ, herpes erodentes, carbunculi, et quæ Chironia et Telephæa vocantur, milleque aliæ ulcerum generationes ab ejusmodi cacoehymia nascuntur. (De temperamentis, lib. iii. Cl. i. p. 45.)

<sup>11</sup> Cutem totiusque corporis partes exagitant lepra, psora, alphas albus, alphas niger, leuce, impetigo simplex, impetigo agrestis, dracontiasis, achrocordones, thymi, myrmecia, clavi calli. Quædam horum ex podagrâ et articulari morbo, quædam ex sese oriuntur....Achores, pityriasis, meliceres, atheroma, et favus. Porro eam partem, quæ capillo tegitur, et mentum occupant, alopecia, ophiasis, calvities, et madarotes. Pili omnes fluunt, extenuantur, quassantur, scinduntur, squalescunt, in pulverem rediguntur, subflavescent, canescunt. (De exterioribus capitis affectionibus. Introductio seu medicus, 117.)

<sup>12</sup> Ἀχῆρ, id est manantia ulcera, cutis capitis vitium sunt, ab ipso sic dicta affectu, quodd cutem tenuissimis foraminibus perforant, ex quibus glutinosa effluit sanies. Huic vitio affine est, quod πυρίον dicunt Græci (nos favum), in quo foramina sunt, quam in illis majora, melleum continentia humorem. (Galenus De remediis paratu facilibus. —7. Classis, t. iii. p. 300.) Aetius (Tetrabibl. cap. 68, lib. ii.) describes impetigo of the scalp under the name of *μελιχρῆς*. M. Alibert has described that of the face under the name of *melitagre*.

<sup>18</sup> Pustulis quæ puero per cutem erumpunt, primum sanè nullum facessere negotium oportet; ubi verò probe decreverint, tunc jam curare tentabimus balneis....optimum verò est nutricem dulciori victu uti. (Pauli Æginetæ Opus de re medica. Lib. i. p. 7. Parisiis, 1532.)

<sup>19</sup> Rhazes. In medicinali disciplina, ch. xxvi. fol. Venitiis, 1542.

<sup>20</sup> Avicenna (In res medicas omnes, &c.) (Venetiis, fol. 1564. lib. iv. fen. i. tract. vi. p. 71, 72 et 73) has well distinguished rubeola from variola: "Variola vero in principio apparitionis est eminentia et altitudo; et morbillus est minor variolis et minus accedet oculo quam variola....Lacrymæ in eo sunt plures...et dolor dorsi minor."

pestilential carbuncle (de pruna et igni persico); his description *de vesicis et inflationibus* appears applicable to pemphigus and rupia, and that *de essera* to urticaria; his *safali* corresponds with our impetiginous eczema of the head and other regions of the body, and his *bothor levis* to rosacea.<sup>1</sup> Avicenna appears farther to have distinguished between scabies and prurigo.<sup>2</sup> Avenzoar speaks of the *acarus scabiei*.<sup>3</sup>

The Arabian physicians, great advocates for blood-letting, have also enriched the *Materia Medica* with a variety of new medicines, and advanced therapeutics by their novel applications of many of those that were already known. They studied the action of baths, particularly of the sulphureous mineral waters, in diseases of the skin.

The writers who come next in order after the Arabian physicians, have left us ample details with regard to the two most remarkable epidemics, that have ever occurred whether the extent of their ravages or the length of time during which they continued be considered. Theodorici<sup>4</sup> and Gilbertus Anglicus<sup>5</sup> were the first who described the *lepra* of the middle ages; Torella,<sup>6</sup> Manardus,<sup>7</sup> Massa,<sup>8</sup> Fracastorius,<sup>9</sup> and many others, make us acquainted with the various forms of *syphilis*.

On occasion of these two memorable epidemics, and with a view the better to fix their characters, Aquilanus,<sup>10</sup> Leoniceus,<sup>11</sup> and some other writers quoted in the *Aphrodisiacus* of Luisinus, such as Montesaurus, Scanaroli and Cataneo, gave more attention than had yet been done to a comparative study of the descriptions of *lepra*, elephantiasis, alphas and leuce, left by the Greek writers, and of elephantiasis and several other diseases of the skin, handed down by the Arabians. These authors remind us of the fact that the translators of Rhazes and Avicenna make use of the word *lepra* to designate the disease entitled elephantiasis by the Greeks; that the *lepra* of the Greeks was a squamous disease, and that the elephantiasis of the Arabians is distinct from both the *lepra* and elephantiasis of the Greeks.

One of the most celebrated surgeons of the period when letters and the sciences began to revive, Guido de Gauliac or Guy de Chauliac,<sup>12</sup> distinguished five species of *tinea*, which correspond exactly with impetigo, eczema, sycosis and favus of the scalp; he characterizes anthracion perfectly, and is the first who speaks of the contagion of scabies.

Vidus Vidius or Guido<sup>13</sup> mentions the vesicular varicella or chicken pox.

Fracastorius, in his treatise *de morbis contagiosis*,<sup>14</sup> endeavours to determine which of the diseases of the skin were contagious, and which were not; he has also distinguished very accurately between *anthrax*, *phyma* and proper *carbuncle* [anthracion?].

Fernelius<sup>15</sup> describes lentigo, and the redness of the skin, the pustules and indurations or tubercles of rosacea; he also gives a particular account of sundry forms of syphilitic eruption; he indicates purpura, or at least spontaneous ecchymosis of the skin; he unites into a single group *impetigo*, the whole of the papular and squamous eruptions, and describes eczema of the scalp under the name of *tinea*.

Forestus,<sup>16</sup> a learned observer, has published a number of particular

cases, among which there occurs one of pemphigus *infantil*, one of contagious scabies, which he distinguishes from a variety of other diseases, all alike designated in his time by the title of scabies, one of psoriasis palmaris, one of *lepra vulgaris*, &c. These cases are accompanied with scholia, in which Forestus examines and discusses the observations of preceding writers relative to cases of a corresponding description.

Schenkii,<sup>17</sup> a laborious and erudite compiler, has brought together a great number of cases of alterations of the hair, of congenital and accidental horny productions, of diseases of the hairy scalp, of sycosis or mentagra, of lichen, &c.

Sennertus<sup>18</sup> describes many of the changes in colour which the skin undergoes, particularly those which are entitled liver-spots (chloasma); as also fetid ephidroses of the feet, axillæ and body at large. He gives a detailed account of the diseases of the hair-follicles and of plica, after Starnigel and other observers.

Ballonius or Baillou<sup>19</sup> revives and comments upon the Hippocratic doctrine of the diseases of the skin, considered now as existing *per seipsis*, now as *ἀνοστασις* or *depositories* or *emunctories*, and again as *vitia loci*.

The essays of Joubertus<sup>20</sup> and Compolongo<sup>21</sup> scarcely deserve to be mentioned.

Mercurialis<sup>22</sup> introduced into his descriptions the observations of the writers who preceded him. Like Galen, he divided the special diseases of the skin into two sections: as they were *peculiar* to the head, or as they were liable to appear on *all parts of the body*. The latter he subdivided into two special groups: as they altered, first, the *colour* of the skin (leuce, alphas, &c.); secondly, as they rendered its surface rough and uneven (impetigo or lichen, pruritus, scabies, or psora, *lepra*), to which he added a variety of tumours, without, however, condescending on the description of any. Under the name of *tinea* he gives the characteristic symptoms of favus (*tinca favosa*; porrigio *lupinosa* Willan) with great clearness,—its bright yellow and dry crusts, its transmission by contagion, and its influence in causing the loss of the hair. He detaches completely and with justice, the disease from *achores* and *favi*, [impetiginous eczema, and impetigo?] the influence of which upon the constitution and anterior diseases, he carefully notes.

Joannes Riolanus,<sup>23</sup> after alluding to this division of Mercurialis, proposes another of his own, based upon the appearances presented by the diseases of the skin, without regard to their seat. The diseases of the skin, says he, may be divided, first, into *pustules* (prurigo, scabies, psora, *lepra*, impetigo, psudracia, ambustio); secondly, into *deformities* (maculæ, morbid discolorations, loss of the hair, phthiriasis); thirdly, into *tubercles* (warts, excrescences, condylomata.)

Hafenreffer<sup>24</sup> describes the diseases of the skin very briefly, and often after the ancient or cotemporary authors, without appearing to have been guided by any general views in their distribution. He includes variola, rubeola, the venereal eruptions, and the primary symptoms of syphilis in the study of the diseases of the skin. There is, in fact, nothing remarkable in his work, especially in comparison with that of Mercurialis, beyond his description of the syphilides or syphilitic eruptions, of dysenteric variolæ, and his history of the *pediculi* of the human body, of which he reckons four species, one of which evidently corresponds to the *acarus scabiei*. He farther attempts to construct a *table of synonyms*, in which the Greek, Latin, Arabian, and German names of the diseases of the skin are included; but, he has here committed a considerable number of errors, and has frequently assimilated

<sup>1</sup> Sparguntur super nasum et super poma maxillarum *bothor* (pustulæ) albæ, quasi ipsa sint puncta lactis.

<sup>2</sup> Et scabies quidem differt a pruritu in hoc quod cum pruritu non sunt *bothor* (pustulæ) sicut sunt in scabie....et pruritus quidem senilis parum obedit curationi.

many very imperfect descriptions, which, nevertheless, refer evidently to diseases widely different.

After a short review of the structure of the skin, Willis<sup>1</sup> divides the diseases to which it is liable, into two sections, as they show themselves *vel cum, vel sine tumore*. The affections *cum tumore* are farther *general* or *particular*. Of the former several invade with fever, variola, rubeola, the exanthemata and efflorescentiæ of infants; others without fever, prurigo, and the impetiginous and leprosy affections. The diseases *sine tumore* include the whole of the maculæ, ephelis, liver-spot, &c. These divisions were natural enough.

Bonetus<sup>2</sup> has gathered together into his useful collection a considerable number of rare cases of cutaneous disease, the greater number of which are taken from the *Ephemerides naturæ curiosorum*,<sup>3</sup> or the *Acta regiæ societatis medicæ Hafniensis*.<sup>4</sup> Imitating the example thus set, Magnetius in his *Bibliotheca medico-practica*,<sup>5</sup> has given a reprint of the work of Willis, quoted above, and by adding many interesting cases of cutaneous disease published by Blandini, Raymondus, J. Forti, B. Sylvaticus, Hagedorn, Rhazes, Schulz, Wedel, A. Saporta, Helwig, and others, has contributed to spread abroad information of much practical value.

Many observers have assisted the progress of cutaneous pathology, by the publication of particular cases, in the *Journals* or periodical *Collections*, with a view to demonstrate the utility of divers modes of treatment, or to make known certain rare forms of affections of the skin. As depositaries of this kind, I must mention the *Centuræ* of Laz. Riverius,<sup>6</sup> the *Observationes* of M. A. Severinus,<sup>7</sup> particularly with reference to Arabian elephantiasis of different parts of the body, and the collections of Zacutus Lusitanus;<sup>8</sup> Stalpartus van der Weil,<sup>9</sup> Felix Platerus,<sup>10</sup> Dodonæus, Benevinius,<sup>11</sup> Borellus,<sup>12</sup> Hagedorn,<sup>13</sup> Philip Hechstetter,<sup>14</sup> &c. More recently, several observers, Duncan,<sup>15</sup>

Reil,<sup>16</sup> De Haën,<sup>17</sup> Gilibert,<sup>18</sup> &c., have published in their *Clinical Reports*, a very considerable number of cases and practical remarks, on the pathology and treatment of cutaneous diseases.

The great merit of the work of Turner<sup>19</sup> is its positive and practical character. In support of the doctrine he advances, he generally quotes one or more cases which he has either met with in his own practice, or which he borrows from the writings of others. He was the first who gave a good description of the various species of herpes (*herp. circinatus*, *herp. phlyctenodes*, *herp. zoster*), which he detaches definitely from herpes *exedens* vel *depascens*, i. e. lupus; he distinguishes the furunculus anthrax from true carbuncle; he gives a curious case after Willis, of the absence of perspiration (anhydrosis); he insists on the danger of suppressing copious or fetid ephidroses; he describes coloured or pigmentary nævi, vascular nævi, and degenerated nævi, and speaks of their treatment by means of the ligature, excision, and the application of escharotics; he relates after Job a Meekren a remarkable case of extensibility of the skin of the neck and breast.

The work of Lorry<sup>20</sup> is distinguished for its general views, and the broad manner in which the author there regards the study of the diseases of the skin. In these particulars, Lorry is undoubtedly superior to all the writers who preceded, and to the greater number of those who have followed him. He begins by studying the general organization and particular structure of the healthy skin; he compares its elements in the different regions of the body, and, after a rapid glance at its functions, he considers its relations with the other systems and organs of the economy. He next passes briefly in review the various modifications which the skin experiences under the influence of external agents—the air, varied temperatures, climates, and applications of all kinds; he then takes note of the effects of the ingesta, food and drink; of rest and exercise; of sleep and watching; of the affections of the mind, &c. He next specifies the influence of whatever is internal or organic, such as of the strumous constitution, of suckling, of the variolous, venereal, morbillary virus, &c., and insists on the necessity of a careful inquiry into the probable causes of each affection. The prognosis he studies comparatively in children, adults, and the aged; he insists strongly upon the danger of repelling cutaneous eruptions, and he revives and develops the Hippocratic division of the diseases of the skin, into those which are determined thither by internal affections, and into those which are produced by a merely local morbid process.

His general views of the treatment of cutaneous diseases are of the very highest interest; he makes us sensible of the necessary and important modifications that must be made in the treatment, according as the eruptions have arisen under circumstances in which they must be considered as critical, depurative, or dangerous to cure; according as they indicate a slow or speedy solution of internal maladies; and lastly, as they are entirely local, and capable of being combated by external or topical means. Lorry's work, so rich in these practical views, is, however, very deficient in particular descriptions of individual diseases; here we constantly feel the want of precision in the determination of species, which are often imperfectly described, in several chapters, and under different names.

Cotemporary with Lorry, Plenck<sup>21</sup> arranged the diseases of the skin into classes, in the hope of facilitating the study of this branch of pathology, and rendering the diagnosis of the individual affections more certain. This classification is founded on the *external appearances* of the diseases themselves, consequently on their most recognizable characters. Plenck formed fourteen classes of cutaneous diseases: 1mo. *Maculæ*; 2do. *Pustulæ*; 3io. *Vesiculæ*; 4to. *Bullæ*; 5to. *Papulæ*; 6to. *Crustæ*; 7mo. *Squamæ*; 8vo. *Callositates*; 9mo. *Excrementia cutanea*; 10mo. *Ulcerata cutanea*; 11mo. *Vulnera cutanea*; 12mo. *Insecta cutanea*; 13mo. *Morbi unguium*; 14to. *Morbi pilorum*.

<sup>16</sup> Reil (J. C.). (Memorab. clinic. faciculi, 8vo. Halæ, 1789–91–92.) Hemorrhæa petechialis; pemphigus; diseases consecutive to measles and small-pox.

<sup>17</sup> De Haën (A.) (Ratio Medendi. Viennæ et Paris.) Variola; inoculation; rubeola; scarlatina; critical and non-critical sweats.

<sup>18</sup> Gilibert (J. E.) (Adversarie medico-practica, 8vo. Lugd., 1791.) Cancer of the skin; scabies; ulcers; variola; pemphigus, syphilis, &c.

<sup>19</sup> Turner (D.). A treatise of diseases incident to the skin, 8vo. Lond. 1714; itrum 1726, &c. Trad. Franc. 12mo. Paris, 1743.

<sup>20</sup> Lorry. Tractatus de morbis cutaneis, 4to. Parisiis, 1777.

<sup>21</sup> Plenck (Joan. Jacob.) Doctrina de morbis cutaneis, quæ hi insuas classes, genera et species rediguntur. Viennæ, 1776, 8vo. Ibid. 1783, 8vo. Lovani, 1796.

The end and object of this classification were evidently to facilitate the diagnosis of cutaneous diseases, not to convey information in regard to their nature, which is not always in relation with their outward appearance; it was, in a word, an artificial method of arriving at the determination, or at the knowledge of species, without which, no study can be rendered precise, and no conclusions can be held rigorous. It is even easy to see that Plenck had no intention of giving a classification of the diseases of the skin according to their nature; it is therefore unfair to reproach him with the diversity of the elements which compose his classes. The classes present imperfections which have arisen more particularly from his not having always stuck with sufficient closeness to what were in fact the most striking external characters of the species which he has arranged together in each of his different groups.

Willan,<sup>1</sup> in his system of classification, starts essentially from the same point as Plenck; but instead of attaching himself, like the German author, to the most striking feature of the diseases of the skin, at any and every period in their progress, he assumes the character which they present at their highest pitch of development—at their *erect* or *height*, and before they have undergone any consecutive alteration, as the element of his distribution. In the majority of cases, the diseases of the skin are much more strikingly characterized at this stage, than they are either before or afterwards, by the appearances which precede or follow them, and which are frequently common to several affections. Willan has, in conformity with this view, suppressed the classes of *ulcers*, *crusts*, &c. His groups are better ordered than those of Plenck. He never mingles, as the latter does constantly, *symptoms* with *diseases*; and a much more accurate knowledge of the eruptions themselves than Plenck possessed, enabled Willan to judge more precisely of their proper places in his different groups. Several of these are even extremely natural, such as the *papule*, the *squamæ*, the *bullæ*, and even the *exanthemata*, if purpura be struck out of it; on the other hand, the *tubercula* includes diseases of the most dissimilar descriptions. The great characteristics of Willan's writings are the impress they bear of the scientific spirit that guided him in his researches; the great precision, and the purity of his descriptions; the particular pains he takes to select well, and to use judiciously, his technical expressions; lastly, the taste and the sound judgment he displays in his interpretation of the ancients. If there be aught with which he is chargeable in the way of omission, it is with having paid too little attention to the relations of the diseases of the skin to the state of the constitution, to anterior diseases, and to those affections which are attributed to their repercussion. His therapeutics is in general active; his practice, his writings, and the works which have issued from his school, contributed powerfully to extend the free use of purgatives, and the internal employment of a variety of powerful medicines, such as the tincture of cantharides, the mineral acids, and the preparations both of antimony and arsenic in the treatment of cutaneous affections.

Bateman, by completing the works of Willan, and reproducing them in an accessible and elegant form,<sup>2</sup> contributed greatly to extend a knowledge of the diseases of the skin. Bateman also in his edition of the atlas, commenced by Willan, gave figures of a considerable number of diseases of the skin.<sup>3</sup>

The works of these celebrated pathologists were recast by Gomez,<sup>4</sup> and published in the shape of a *synoptical* table of the diseases of the skin; by Em. Szalay<sup>5</sup> in his inaugural dissertation, in the form of a *Manual*; and by Bertrand<sup>6</sup> and Ab. Hanemann and Sprengel,<sup>7</sup> who spread a knowledge of them over France and Germany.

<sup>7</sup> Praktische Darstellung der Hautkrankheiten nach Willan's System bearbeitet

The little work of Retz<sup>8</sup> has no pretensions to a scientific character; it is simply a collection of notes, and of cases, concisely detailed, having for the most part a practical end. It includes instances of cheloid tumour, of strumous tetter, of eruptions about the genital organs of men and women, and a variety of observations on the constitution, and on the physical and moral character of individuals habitually subject to herpetic affections. The author speaks of the influence which diseases of the skin of the face exert on the tastes and habits of females of a certain age; he mentions the relations of the diseases of the skin to gout and the affections of the urinary organs; he dwells on the difficulties almost always connected with the treatment of cutaneous diseases, and the frequency of relapses among individuals who will not consent to follow the course prescribed, whether it be medicinal or dietetic, in every the most minute particular.

At a time when almost all the chronic diseases of the skin of the face, trunk and extremities, were designated in France under the name of *dartres*, which corresponds to the English word *tetter*, and was interpreted by the Latin term *herpes*, the college of medicine of Lyons proposed as the subject of a prize: To determine the various species of *tetter*, their causes, their symptoms, and the diseases that depend on them. The prize was awarded to the dissertation of H. J. A. de Roussel.<sup>9</sup> Sauvages<sup>10</sup> had admitted nine species of *tetter* (independently of *psyracia*, *hydræa*, *epinyetis*, *rosacea*, *ephelis* and *vitiligo*); comprising, 1st, furfuraceous tetter; 2d, crusted tetter; 3d, milary tetter; 4th, eating tetter; 5th, syphilitic tetter; 6th, garter-like tetter; 7th, collar-like tetter; 8th, pustular tetter (*Dart. boutonniée*); and 9th, *zona*. The species admitted by Roussel are in general better characterized, and bear greater affinity to those which are still described at the present day under other names. Under the head of *herpes furfuraceous*, he evidently includes the papular and squamous affections; in his *squamous running tetter* or *dartre vive*, we recognize the characters of excoriated eczema, and his crusted tetter corresponding to our impetigo. Roussel endeavoured to discover and to point out the signs by means of which we may ascertain whether a cutaneous eruption is the depository, as it were, the crisis or the solution of an internal disease, or exists *per se*; and this forms one of the striking characteristics of his work, which is further remarkable for the efforts the author makes to approximate and bring into harmony the imperfect descriptions of his predecessors, rendered still more obscure by the diversity of nomenclature universally employed.

The small treatise of Poupert<sup>11</sup> has no interest otherwise than as it contains several observations on the repercussion and on the metastases of chronic diseases of the skin, and even the greater number of his facts are derived from the writings of Ballonius, Mead, Sauvages, Raymond, Tissot, &c. The instances he gives are dysuriæ, leucorrhæas and affections of the brain and lungs, supervening on the cure of cutaneous eruptions. Poupert also studied the action of the anemone pulsatis in cases of tettery eruption, and quotes several instances of its efficacy in their cure.

Jackson<sup>12</sup> has treated at great length of the *causes* and of the *nature* of the diseases of the skin; which he nevertheless only considers in a very vague and general manner. He divides them into *three* groups; 1st. Morbid secretions of the subaceous glands; 2d. Morbid states of the bulbs of the hair; 3d. Morbid conditions of the cutaneous vessels.

Chiarugi<sup>13</sup> limits his researches to the chronic and *crusted* (*sordide*) diseases of the skin. He divides them into three orders: 1st, crusted papular diseases (impetigo, herpes); 2d, crusted phlyctenoid diseases (achor, rognæ); 3d, crusted pustular diseases (gotta rosea, lepra, tinea). Under the name of *impetigo*, in the first group, he describes liehen pretty accurately, and gives a good definition of the disease; and, under the name of *herpes*, he includes the same diseases as the

<sup>13</sup> Chiarugi (Vincenzo) Delle malattie cutanee sordide in genere e in specie, trattato teorico-pratico, 2 vol. 2da edizione.—Firenze, 2 vol. 1807.

ancients (*herpes miliaris*, *herpes zoster*, *herpes esthiomenes*). In the second group he describes, under the name of *achor*, eczema and impetigo of the face and hairy scalp, and scabies under the title of *roga*. The third group comprises *rosa*, or rosacea; *scabia*, which appears to be eczema; *lepra*, that is to say *lepra gracorum* and elephantiasis and *tigna*, the account of which corresponds to the furfuraceous, crusted and humid states of eczema and impetigo of the scalp. In a word, the work of Chiarugi, although posterior in point of time, is immeasurably inferior to that of Willan.

Wilson<sup>1</sup> divided the diseases of the skin into, 1st. Febrile eruptions (urticaria, miliary eruption, varicella, variola, vaccina, pemphigus, rubeola, scarlatina). 2d. Simple inflammations (excoriations, burns, chilblains, &c.). 3d. Constitutional inflammations (erysipelas, efflorescentiae, rednesses of the face, &c.). 4th. Papular eruptions. 5th. Vesicular eruptions (scabies, eczema, zona, herpes, aphthæ). 6th. Pustular eruptions (pustular scabies, impetigo, porrigo, crusta lactea). 7th. Infantile eruptions (strophulus). 8th. Squamous eruptions (lepra, psoriasis, syphilitic blotches, elephantiasis). 9th. Tumours (acne, follicular enlargements, furuncles). 10th. Excrescences (corns, warts). 11th. Spots (lentigo, ephelis, purpuræ, nævi). 12. Wounds. 13th. Ulcers (simple ulcer, depressed ulcer, callous ulcer, fungous ulcer, syphilitic ulcer, scorbutic ulcer, scrofulous ulcer). In an appendix he makes a number of remarks on the spontaneous disappearance of certain cutaneous eruptions which was followed by various nervous symptoms. One of the inherent vices of this classification is its want of unity; this, however, is a reproach that may be made to almost all the systems of classification of the diseases of the skin that have yet been proposed. In the formation of his groups, the author has attended at once to the nature of the diseases, to their relations with the constitution, and to their outward appearances. A more serious objection may be raised to the mode in which some of his groups are composed; though we must still allow that the first group, were erysipelas added to it, would be extremely natural.

Mr. Plumbe<sup>2</sup> not very long ago published a new distribution of the diseases of the skin. The first section includes those diseases which derive their distinguishing characters from *local peculiarities* of the skin (acne, sycosis, porrigo); the second section comprises such diseases as depend on a *debilitated state* of the constitution, and, consequently, on a *diminution of tone in the vessels of the skin* (purpura, pemphigus, ecthyma, rupia). Sundry diseases, *generally beneficial* in their influence, symptomatic of derangement of the digestive organs, and characterized by active inflammation, form a *third* section (porrigo *favosa*, porrigo *larvalis*, lichen, urticaria, herpes, furuncle). A fourth section or group is characterized by a *chronic inflammation of the vessels which secrete the epidermis* (lepra, psoriasis, pityriasis, pellagra, ichthyosis, warts). A fifth and concluding section, comprises a host of diseases of the most dissimilar character (scabies, eczema, elephantiasis, erythema, &c.). There is unquestionably considerable ingenuity in several parts of this arrangement; but it is inferior to that of Willan. Mr. Plumbe's work, in other respects, is distinguished for its practical character, and for the importance which the author attaches to the connection of diseases of the skin with morbid states of the constitution.

M. Derien<sup>3</sup> divided the diseases of the skin into *acute* and *chronic*, and, as grounds of a subdivision, proposed their distinction into *essential* and *symptomatic*. Both Peter Frank<sup>4</sup> and Joseph Frank<sup>5</sup> adopted the division of the diseases of the skin into *acute* (exanthemata) and *chronic* (impetigines). But this system, rigorously applied, frequently and necessarily leads to the discussion of one and the same disease in two different sections, according as it happens to be evolved slowly or speedily, and to run its course tardily or rapidly. We consequently find *acute* urticaria placed by Joseph Frank in a first class under the usual title, *urticaria*, and the *chronic* affection in a

second, under the name of *urticatio*. *Acute* pemphigus is described in one section under the name of *bullæ*, and the *chronic* disease in another, under that of *pemphigus*. Against this view of Jos. Frank, it may also be shown that erythema, strophulus, herpes, ecthyma, mucifluent tinea, &c., are by no means uniformly chronic diseases, and that furuncle is not always acute. J. Peter Frank divides the *exanthemata* into *naked* and *scabrous*, and the *impetigines* into such as are confined to the *superficies* of the skin, and such as penetrate more *deeply*. Joseph Frank has described, almost without order, the various cutaneous affections arranged by J. P. Frank, in these two divisions. The secondary division which he has adopted of cutaneous affections into idiopathic and symptomatic is inapplicable in any system of classification as a basis for the formation of sub-orders; the distinction, however, is in itself of real value when applied to each disease in particular.

M. Alibert,<sup>6</sup> whose works have obtained so much celebrity, has attempted to connect the diseases of the skin into *families*. 1st. Teignes (T. faveuse, T. granulée, T. furfuracée, T. amiantacée, T. muqueuse).—2d. Pliques (P. multiforme, P. solitaire, P. en masse).—3d. Dartres (D. furfuracée, D. squameuse, D. crustacée, D. rongeante, D. pustuleuse, D. phlycténoïde, D. erythémoïde).—4th. Ephélides (E. lentiforme, E. hépatique, E. scorbutique).—5th. Concroïdes ou keloïdes.—6th. Lèpre (L. squameuse, L. crustacée, L. tuberculeuse).—7th. Pians (P. ruboïde, P. fongoïde).—8th. Ichthyoses (I. nacrée, I. cornée, I. pellagre).—9th. Syphilides (S. pustuleuse, S. végétante, S. ulcérée).—10th. Scrofules (S. vulgaire, S. endémique).—11th. Psorides (P. pustuleuse purulente, P. pustuleuse vésiculeuse, P. papuleuse, P. crustacée). No writer has seized with greater acuteness than M. Alibert, the various aspects of these diseases, nor has any one painted their principal characters in happier colours. His description of the teigne *faveuse* (favus), of the dartre *rongeante* (lupus), of the keloïde, of the dartre *squameuse humide* (discharging eczema), of scrofula, of the different syphilitic eruptions, &c., deserve to be particularly enumerated for their excellence. The work of this writer recommends itself to us farther, by the remarks and practical views, replete with interest, and the vast number of particular cases it contains, calculated to exhibit rare appearances presented by different forms of cutaneous disease, to demonstrate the efficacy of a variety of therapeutic means, and to show the salutary influences occasionally exerted by cutaneous eruptions on the general health, or to prove the dangers which attend on their repercussion. Still more recently, M. Alibert has published another and a more complete work,<sup>7</sup> in which he proposes a new classification of the diseases of the skin. The first (*dermatoses eczémateuses*), comprises the *inflammatory diseases*; the second (*dermatoses exanthémateuses*), consists of *febrile eruptions*; the third (*dermatoses teigneuses*), is formed of the affections of the hairy scalp; the four succeeding groups include *constitutional* affections, to wit, the fourth (*dermatoses dartreuses*), chronic eruptions, common to every part of the integuments; the fifth (*dermatoses cancéreuses*), cancerous affections; the sixth (*dermatoses lepreuses*), the squamous diseases; the seventh (*dermatoses varioleuses*), the variolous eruptions; the eighth (*dermatoses strumeuses*), the scrofulous affections; the ninth (*dermatoses scabieuses*), is distinguished by the general character of the diseases it includes to cause pruritus over the surface of the skin; the tenth (*dermatoses hémateuses*), includes ptechie and purpura; the eleventh (*dermatoses dyschromateuses*), comprises changes in the colour of the skin; the twelfth (*dermatoses hétéromorphes*), takes in various alterations not assigned or unassignable to any of the other classes. This classification<sup>8</sup> is deficient in unity of principle. The groups are evidently formed, now after the inflammatory character of the diseases,

<sup>6</sup> Alibert. Précis théorique et pratique sur les maladies de la peau, in 8vo. 2 vol. première édit. Paris, 1810. 2nde édit. Paris, 1822. Description des maladies de la peau observées à l'hôpital Saint Louis. Paris, 1825, fig. fol.

<sup>7</sup> Alibert. Monographie des Dermatoses, 2 vols. 8vo. Paris, 1832.

<sup>8</sup> Dr. Paget, in an essay on the advantages of the natural, compared with the artificial, method of classification in the study of the diseases of the skin, (in the Edinb. Med. and Surg. Journal, vol. xxxix. 1833, p. 255,) has endeavoured to prove that the classification of Alibert was natural. This opinion has been successfully combated by M. Ch. Martins, in his dissertation entitled, Les préceptes de la méthode naturelle appliqués à la classification des maladies de la peau, 4to. Paris, 1834, who ought, however, at the same time to have acknowledged that the arrangement of Willan was artificial; he might still have demonstrated its superiority. M. Baumés, in his Lettre d'un Médecin de Province aux dermatophiles des Hôpitaux de Paris, 1834, has over-

<sup>4</sup> Frank (Joan. Petr.). De curandis hominum morbis epitome. Mannheim et Vienne, 1792.

<sup>5</sup> Frank (Joseph). Præceps medicæ universæ præcepta, 8vo. Taurini, 1821.—Vol. iii. iv. De morbis cutis.

now after their febrile character; again, from their seat, again, from their causes, &c. It is, besides, enough to cast the most cursory glance over the titles of the different diseases included in the several groups to be made aware of the heterogeneity of the elements that enter into several of them; an inconvenience which is not made up for, as in the classification of Willan, by the accrual of real advantages as concerns the diagnosis. These groups, moreover, with the exception of the two comprising the syphilitic and the strumous affections, have little value in a practical point of view.

Messrs. Cazenave and Schedel<sup>1</sup> have adopted the classification of Willan, but without assigning any place in the system to lupus, pellagra, the syphilitic eruptions, purpura, elephantiasis arabica and the cheloid formation. Their work is constructed on the same plan as that of Dr. Bateman, and like his, contains a very good summary of the principal diseases of the skin.<sup>2</sup> It is enriched with the observations of M. Bielt on lupus and the syphilitic eruptions, which are here described with particular care. It also contains the results of this practitioner's experiments with the iodurets of mercury and sulphur, the action of which on the economy, and the circumstances under which they may be advantageously used, he was the first to study. Like the English pathologists and M. Bielt, the Messrs. Cazenave and Schedel are bold in their recommendation internally of many very active medicines, such as the tincture of cantharides and the preparations of arsenic, in the treatment of the more inveterate and rebellious chronic diseases of the skin.

The work of M. Gilbert<sup>3</sup> has a greater show of erudition than that last mentioned, and contains several concise but well chosen cases, and interspersed remarks of a practical character on the diseases of the skin, considered in their relations with the constitution and the various morbid states it exhibits. His classification, in conformity with that of Willan, has its inherent advantages and inconveniences.

In a systematic *synopsis* Struve<sup>4</sup> has specified almost every known variety of disease of the skin. Mr. Wilkinson<sup>5</sup> has made several pertinent remarks on the treatment of the diseases of the skin; the tract of Mr. Kelson<sup>6</sup> is without interest.

M. S. Grimaud<sup>7</sup> has divided the diseases of the skin into five orders; 1st, diseases of the corpus reticulare; 2d, diseases of the papillæ; 3d, diseases of the infundibuliform cavities; 4th, disease of the follicles.

Baker has proposed to divide the diseases of the skin into two classes, one of which, the *epidermic* diseases, includes the squamous, vesicular and bullous affections, and the other,—the diseases of the *dermis*, embraces our papulæ, tubercula and pustulæ. Dr. Craigie<sup>8</sup> has likewise given a distribution of the diseases of the skin upon anatomical grounds which corresponds very nearly with that of Willan.

Mr. Dendy<sup>9</sup> has attempted a classification of cutaneous diseases,

the utility of which is more especially apparent when children are their subjects. His distribution comprises the following classes: 1st, diseases symptomatic of derangement in the alimentary canal; 2d, diseases symptomatic of disorders in the functions of assimilation; 3d, diseases symptomatic of external excitement or stimulation, and of particular idiosyncrasy; 4th, diseases produced by specific contagions; and 5th, local diseases without constitutional derangement.

M. Ch. Billard<sup>10</sup> has also made some observations on the cutaneous diseases of children, which he distributes after the classification of Willan.

Messrs. Unger<sup>11</sup> and J. L. Schönlein<sup>12</sup> have imagined that they could discover certain relations between the diseases of the skin and what they entitle the *exanthemata* of plants.

J. Fantonetti<sup>13</sup> has made important additions to the subject of pellagra in the translation which he has given of the 1st edition of my work, which has also been rendered into English by Mr. Dickinson<sup>14</sup> with the suppression of the particular cases, with a view to making it more elementary.

To complete this review of the works of those who have contributed by general observations, the publication of particular facts, by their special studies, and treatises *ex professo*, lastly, by their critical and learned investigations and their elementary works to illustrate or render more easy the study of the diseases of the skin,<sup>15</sup> I ought still to mention a great number of *monographs* on almost every one of these diseases individually, and a variety of memoirs containing therapeutical experiments. But as the value of these references will be greatly increased by being given in connection, either with the general and preliminary considerations on the treatment of the acute and chronic inflammatory affections of the skin, or in the *Historical Notices* that will be found at the end of the description of each particular disease, I shall reserve them for these places. Let me in this place, however, mention the researches of Dazille<sup>16</sup> on the diseases of the skin in the negro; those of Wilson<sup>17</sup> on the same class of affections among the Hindoos, and the admirable observations of Adams<sup>18</sup> on morbid poisons (a).

(a) To the above we may add A short Treatise on the External Characters, Nature and Treatment of the different forms of Porrigio or Scalled Head and Ringworm. By Walter Dick., d. 1838. *Nouvelle Dermatologie, ou Précis théorique et pratique sur les Maladies de la peau*, &c. Times deux, 1842. Par P. Baumes. Manual of Diseases of the Skin. From the French of MM. Cazenave and Schedel. With notes and additions by Thomas H. Burgess, M. D., 1842. A Practical and Theoretical Treatise on the Diagnosis, Pathology, and Treatment of Diseases of the Skin, &c. By Erasinus Wilson. London, 1842. Philadelphia, 1843.

looked the advantages of Willan's classification, erroneously disputed the utility of determining *species*, and gratuitously supposed that those who adopted the grounds of this arrangement look no heed of the other appearances of the diseases of the skin, in exposing their characters and establishing their diagnostic features. Otherwise, he insists with reason on the importance of the study of the causes, and of the various conditions which precede or accompany the development and progress of diseases of the skin.

<sup>1</sup> Cazenave et Schedel. *Abrégé pratique des Maladies de la Peau*. 8vo. Paris, 1828. 2me edit. ib. 1833. English translation, Philadelphia, 1829.

<sup>2</sup> The work of these gentlemen is indeed all that Dr. Rayer says it is. But let us here do Dr. Rayer the justice which he has not done himself. The *Abrégé Pratique* of Cazenave and Schedel, is an abridgment of the first edition of this, his own work, with the additions and alterations he indicates. There is another work published in England so recently that Dr. Rayer could not be aware of its existence, which owes much to the same source whence Cazenave and Schedel drew. As a manual it is every way superior to the *Synopsis* of Bateman, and has the advantage over the *Abrégé Pratique* in having been written by an individual intimately acquainted with the subject. This is "A practical compendium of the Diseases of the Skin, by J. Green, M. D." 8vo. Lond. 1835. R. W.

## ON THE

# D I S E A S E S O F T H E S K I N .

### CLASSIFICATION.

1. In this work I comprise, under the general title of DISEASES OF THE SKIN, every morbid condition which shows itself on the exterior of the body by some distinguishing character. Many of these affections are preceded, accompanied or followed, by lesions of one or more of the other tissues, and occasionally by modification of the general circulating fluid; the alteration of the skin, which is assumed as characterizing them, is, in fact, only one of their more evident features.

2. The study of the diseases of the skin demands, as a preliminary, a knowledge of its general conformation, of its intimate structure, and of its functions. Diseases of the integuments at large naturally fall under two grand divisions—as they affect the skin itself, or the parts which are connected with it.

3. The skin may be the subject of wounds, of acute and chronic inflammation of different kinds, of anemia, hemorrhage and congestion, of neuralgic pain, of accidental blanching and discoloration, of original faulty conformation, and of changes of texture from the effects of disease. The parts dependent on the skin—the nails and hair—occasionally also present unnatural appearances, consequent on morbid alterations in the structures that prepare them. Moreover, several insects are found living and reproducing their kind on the surface and in the substance of the integuments.

4. The following table presents, at one view, the names of the principal alterations of the skin and its dependencies, and the order in which they will be successively described. Wounds, being within the domain of pure surgery, will not be noticed in this work. I should also have abstained from speaking of certain other affections, entirely foreign, in their commencement at least, to the skin, had their true seats been more generally known, and had I not hoped to throw some light on their nature and treatment. I have not, however, thought it advisable to introduce into the table the titles of several diseases which are still but little understood, such as the Aleppo pustule, Radesyge, Frambæsia, &c., the description of which I have inserted in the appendix that will be found at the end of the work.

TABLE.

DIVISION I. Diseases of the Skin.	CHAPTER I. Inflammatory af- fections, distri- buted according to the number and form of their elementary le- sions.	SECTION I. Having a single ele- mentary form.	1. EXANTHEMATA.—Erythema, ery- sipelas, tubercula, roseola, scarlatina, urticaria; artificial exanthemata. 2. BULLE.—Pemphigus, rupia; arti- ficial bullæ—blisters, ampullæ. 3. VESICULÆ.—Herpes, eczema, hy- drargyria, scabies, miliaris sudato- ria, (suetie militaire,) sudamina; arti- ficial vesicles. 4. PUSTULÆ.—Variola, varicella, vac- cinia, vacciniella, acne, rosacea, syccosis, impetigo, favus, ecthyma; artificial pustules. 5. FURUNCULI.—Hordeolum, furuncu- lis, anthrax. 6. GANGRENÆ.—Anthraxion vel pus- tula maligna, anthrax pestis. 7. PAPULÆ.—Strophulus, lichen, pru- rigo; artificial papulæ. 8. SQUAMÆ.—Pityriasis, psoriasis, le- pra, pellagra; artificial squamæ. 9. TUBERCULA.—Lupus, scrofula, can- cer; elephantiasis Græcorum; arti- ficial tubercles.

#### DIVISION I. Diseases of the skin.

CHAPTER II. Peculiar states of the skin not re- ferable to in- flammation.	SECTION II. Having se- veral ele- mentary forms.	1. SYPHILIS. 2. AMBUSTIO. 3. PERNIO.	Exanthematica, bullo- sa, vesiculosa, pus- tulosa, squamosa, pu- puloa, tuberculosa, vegetativa. Exanthematica. Bullosa. Gangrenosa. Exanthematica. Bullosa. Gangrenosa.
CHAPTER III. Morbid states of the secreting functions of the skin.	ANEMIE. CONGESTUS SANGUINEL. HÆMORRHAGIE.		Purpura (Petechiæ, Vi- bices, Ecchymoses, Dermatorrhagia).
CHAPTER IV. Neuroses of the skin.	PERSPIRATIONIS. Ephidros. EPIDERMIDIS. Exfoliatio.		
	ANÆSTHESIA, Hyperæsthesia.		
	PIGMENTI (Achromata; Dyschromata).		Albinismus seu Leuco- pathia. Nigrities, Ephe- lis, Lentigo, Chloasma, Melasma, Nævus pig- mentarius, Color cæru- leus, Color sub flavus; artificial discolorations.
CHAPTER V. Faulty structure, or unusual states of one or other of the elements of the skin.	PAPILLARUM et epider- mis. HYPERTROPHIE Vasorum cutis. GANGRENA SIM- PLEX. CICATRICES. DEFECTUS CON- GENITUS CUTIS. EXTENSIO VEL RELAXATIO IN- SOLITA CUTIS.		Ichthyosis, Verruca, Producta comea, Ty- losis. Phlebeetasia, angiecta sia capillaris, Nævus araneus, flammeus, &c. Tumor vascularis.
	CORII, Mem- branae Cel- lularis sub- cutaneæ, et teles adipo- sæ.		Cheiloidea, Tumores vari, Elephantiasis arabica, Andrum et Pedarthoræ Barba- does Leg. &c.
CHAPTER VI. Degenerations.	DEGENERATIONES FIBROSÆ. MELANOSIS. DEGENERATIONES TUBERCULOSÆ.		

#### DIVISION II. Alterations of the dependen- cies of the skin.

CHAPTER I. Special diseases of the Sebaceous Follicles.	CHAPTER II. Special diseases of the piliferous follicles.	CHAPTER III. Special diseases of the ungual matrices and al- terations of the nails.
Secretio aucta, Vermes sebaci, Levatio follicularis, Tumor follicularis, Calculi folliculorum.	Atrophia, defectus congenitus pilorum. Pili supernu- merarii; Incrementum insolitum Pilorum, Coactio, pilorum, Alopecia, Canities, Plica.	Onychia, Vicia conformationis et structuræ unguium; Ecchymosis subunguealis; Incrementum insolitum Unguium; Situs insolitus; Ficus; Defectio, dege- neratio; Productio et Reproductio, &c.

#### DIVISION III. Foreign bodies on the surface, under, or in the substance of the skin.

PARASITIC INSECTS infesting the skin of man.
Pediculi; Pulices; Acarus Scabici; Filiaria medi- nensis; Oestrus.

5. All the diseases specified in these different groups show themselves on the external surface of the integuments by distinguishing characters. In all, the skin is affected in a greater or less degree; but some of them are also preceded or accompanied by febrile symptoms, and by other functional organic lesions. Lastly, a great many of them, independently of the alterations of the skin, by which they are outwardly proclaimed, are evidently connected with morbid conditions of the blood, of the nervous system, or of some internal organ or system of organs. Diseases of the skin require, therefore, to be studied more deeply than in their mere external appearances.

# FIRST DIVISION.

## DISEASES OF THE SKIN.

### CHAPTER I.

#### INFLAMMATORY AFFECTIONS OF THE SKIN.

##### PRELIMINARY CONSIDERATIONS.

6. I COMPREHEND, under the generic title of *Inflammation of the Skin*, all those diseases which are characterized, externally, by the accumulation of blood in a point, a district, or the whole of the surface of this membrane, become the seat of morbid sensations: a phenomenon which is followed by resolution, desquamation, adventitious secretion or ulceration.

7. These diseases, as numerous as they are various, studied generally in their external characters,—those characters, namely, which are at once the most easily appreciated,—present themselves, when at their height, under aspects that are reducible to eight principal forms:

1°. *Exanthemata*, distinguished by a generally diffused red tint of the skin; or by red, or reddish distinct blotches, scattered over its surface, and terminating by resolution, delitescence or recession and desquamation.

2°. *Bullæ*, or small, aqueous, and generally transparent vesications, formed by an effusion of serum or coagulable lymph beneath the raised epidermis.

3°. *Vesicles*, or small serous, transparent elevations, differing from bullæ in their inferior size, and formed by a small quantity of serum, with or without coagulable lymph, deposited under the epidermis. This serum, or lymph, may be again absorbed, or by the rupture of the vesicles, be effused upon the surface of the skin. Vesicles are followed by desquamation, by superficial excoriations, or by small, thin and laminated scabs or crusts.

4°. *Pustules*, or elevations formed by pus, or a morbid matter differing from serum, deposited either in a follicle under the epidermis, or in the texture of the true skin. Pustules commonly dry off into hard, thick scabs, which occasionally conceal excoriations or ulcers of variable depth.

5°. *Papulæ*, or hard and solid elevations, almost always attended by itching. They end in resolution or desquamation, when their heads are not picked off by the nails, in scratching.

6°. *Squamæ*, formed by laminae of the epidermis, altered and dried, which are continually detached from the surface of the inflamed skin.

7°. *Tubercles*, or small solid, circumscribed, and enduring tumours, larger than papulæ. They terminate in resolution, induration, partial suppuration or ulceration.

8°. *Furuncles*, or solid tumours, larger than tubercles, developed in the subcutaneous cellular tissue, and in the interspaces of the

skin. They terminate by suppuration with the expulsion of a core or sloughy substance.

8. These various forms cannot be regarded as degrees of one mode of irritation; for they are not all seen changing the one into the other, under the influence of artificial and graduated forms of irritation. Many of them are developed in distinct elements of the skin, and constantly display the same characters when they return, after having disappeared during a longer or shorter space of time. The special cause, under the influence of which an inflammation of the skin appears and produces a vesicle, rather than a pimple or a scale, is as yet unknown.

9. All inflammatory affections of the skin, except those that are designated *gangrenous*, and whose elementary form varies and is little known, may be easily referred, during the period they remain at their height, to one or to several of these forms, the characters of which are definite and readily appreciable.

##### FORMS OF CUTANEOUS INFLAMMATION.

###### § 1. Having a single elementary form.

(A) *Exanthematous*, diffuse or spreading inflammations—Erythema, erysipelas, rubeola, roseola, scarlatina, urticaria, artificial exanthemata.

(B) *Bullous*, or effusive inflammation.—Pemphigus, rupia, phlyctenæ, artificial bullæ, blisters, ampullæ.

(C) *Vesicular* inflammations.—Herpes, sudamina, eczema, hydrargyria, scabies, miliaria sudans, artificial vesicles.

(D) *Pustular* inflammations.—The variolous eruptions,—variola, varicella; the vaccine eruptions,—vaccinia, vaccinella; gutta rosea, aene, sycosis, impetigo, favus, ecthyma, artificial pustules.

(E) *Furunculous* inflammations.—Hordeolum, furunculus, anthrax.

(F) *Gangrenous* inflammations.—Anthraxion, malignant pustule or Persian fire; gangrenous carbuncle, typhoid inflammatory gangrene.

(G) *Papular* inflammations.—Strophulus or gum, lichen or sunrash, prurigo or itchy-rash, artificial papulæ.

(H) *Squamous* inflammations.—Pityriasis or dandriff, psoriasis or scaly tetter, lepra or scaly leprosy, pellagra, artificial scaly inflammations.

(I) *Tubercular* inflammations.—Lupus, elephantiasis, scirrho-carcinoma or cancer, artificial tubercles.

###### § 2. Having several elementary forms.

(A) *Burns*.—Exposure to excessive temperature is followed by exanthematous, bullous, or gangrenous inflammation.

(B) *Frost-bite*.—Exposure to very low temperature is, also, succeeded by exanthematous, bullous, or gangrenous inflammation.

(C) *Syphilitic affections* produce exanthematous, vesicular, bullous, pustular, papular, scaly, tubercular, and forms of inflammation attended with morbid growths.

10. I have already noticed the chief defects of this classification.

The most important, undoubtedly, is that of uniting, under several particular groups, affections which are foreign to each other in their progress, their tendency, and their mode of treatment; and of separating others, such as the *eruptive fevers*, which have so striking an analogy with each other. These serious inconveniences, which I wish not to conceal, are counterbalanced, however, by the facility and precision of the diagnosis we are enabled to establish by means of the artificial arrangement adopted: and this, on reflection, appears to be the principal, and perhaps the only advantage to be expected, in the present state of knowledge, from nosological classification<sup>1</sup>

11. *Ulcers*.—In the above enumeration of the inflammatory affections of the skin, I have made no mention of ulcers. These, in fact, constitute no primary alteration, or initiatory form of cutaneous disease. They are always consequent on subcutaneous abscesses, or on vesicular, pustular, tubercular, or some other form of inflammation. Moreover, the description of ulcers cannot be detached from the discussion of the various inflammations that produce them. I have, for the same reason, connected the description of chaps and fissures with the account of the diseases that occasion them,—erythema, eczema, lichen, psoriasis, syphilitic affections, &c.

12. *Scabs and crusts*.—Neither can these, which are formed by matters deposited and dried on the surface of the skin, whether ulcerated or not, be assumed as the distinguishing character of a genus. Independently of this, that, before being *encrusted*, diseases are vesicular, pustular, bullous, &c., a group formed after such a circumstance, would have been more vague than any of those we have adopted. Studied, however, as secondary phenomena, these crusts, in their mode of formation, their dimensions, their colour, their adherence, &c., present particulars calculated to characterize certain species—favus, rupia, &c.

13. The chemical analysis of the morbid liquid or dried secretions, poured out by the diseased skin, can only furnish characters of a very secondary interest; and yet the analyses that have been made of the vaccine lymph, of the true or modified variolous matter, of the matter of favus, of melanosis, &c., prove incontestably that no mode of investigation whatever is to be contemned.

14. The same remark is applicable to several other consecutive alterations. Thus, the dark stains formed by the deposit of a larger quantity of blood than natural in the tissue of the skin; the bran-like desquamation of the epidermis, caused by certain papular or vesicular inflammations; the cicatrices which variola, zona, rupia, vaccinia, lupus, ulcerated syphilitic eruptions, &c., leave, all present characters that immediately proclaim their origin to the practised eye.

15. When inflammation extends from the skin to the mucous membranes, they sometimes distinctly present the same forms of phlegmasiæ as the skin itself. The difference of structure, however, of these two grand divisions of the cutaneous system, necessarily introduces modifications into the mode of development, and the appearance of the various forms of inflammation affecting their surface. Farther, the symptoms peculiar to each of these different forms, though easily appreciated in the skin, are much more obscure in the mucous membranes.

16. *Local symptoms*.—Some, among the inflammations of the skin, are constantly either acute or chronic in their progress; others, again, according as the exciting cause is permanent or temporary, present themselves in the one or in the other of these forms.

17. The most constant local phenomena of inflammation, *redness*, *pain*, *heat*, and *swelling*, exhibit a multitude of shades and varieties in the cutaneous phlegmasiæ, which I shall discuss in detail, when I give the history of each individually.

18. Redness is a constant phenomenon, whether it constitute the most evident character of the inflammation, as in the exanthemata, or is not readily to be appreciated, except before the formation, or after the rupture of vesicles, of bullæ, and of pustules, or after the fall of scabs and scales. The distinguishing character of this redness, slight and fleeting in roseola, bright and flushing in scarlatina, is, that it disappears on pressure, but quickly returns when the pressure is re-

moved. It is only in some cases, forming exceptions, but which occur more frequently than is generally imagined, that the redness does not entirely disappear. A certain quantity of blood has then been effused beneath the skin, which, when the redness goes off, leaves behind it, especially in vesicular, pustular, and bullous inflammation, brownish or yellowish stains, which are obliterated in the course of time.

19. Itching, heat, scalding, burning, tension, gnawing, &c., are so many forms under which the pain of the inflamed skin may show itself. To each of them belong a number of shades, which are characteristic of several varieties of disease; the pruritus, for instance, has particular characters in itch, prurigo, eczema, and urticaria; the sense of heat, sharp in erysipelas, hot and burning in scarlatina, is still more troublesome in hydrargyria. Lastly, if several cutaneous phlegmasiæ are accompanied by violent and intolerable pruritus, others do not commonly excite the slightest sensation of itching; amongst these are the syphilitic eruptions.

20. The inflamed skin no longer communicates the soft and moist sensation of warmth, which is peculiar to the healthy state. An increase of heat is appreciable by the thermometer, in the greater number of acute inflammations, especially in scarlatina and hydrargyria; but is not perceptible in chronic inflammations. With regard to the sensations of the patient, the heat, to him, appears slight, intense, gentle, or pungent and biting, and often much greater than it is in fact.

21. The tumefaction of the skin, very conspicuous in some acute inflammations,—as erysipelas, urticaria, variola, erythema nodosum, anthrax, &c., is little appreciable in others,—as roseola, pityriasis, &c. The apparent tumefaction of the skin, in the greater number of cases, is owing, at least in part, to that of the corresponding subjacent cellular tissue.

22. The functions of the skin are always more or less implicated in acute inflammations of its substance. The *cutaneous perspiration*<sup>2</sup> may be diminished or suspended,—as in the height of the eruption of scarlatina; or augmented, as in the sweating miliaria, (*suette miliaire*); or modified in its sensible and chemical properties. The secretion of the *oily fluid*,<sup>3</sup> which, in health, is poured out upon the surface of the skin, is entirely suspended in the parts affected with squamous inflammation. This want of secretion is especially remarkable in the pityriasis of the hairy scalp, and in the scaly patches of lepra and psoriasis inveterata. The secretion of the *sebaceous* matter is likewise interrupted, under the same conditions; but it is evidently increased in one variety of acne, viz., the punctata; it is, farther, modified in certain impetiginous affections, in which the matter, having more the appearance of honey, or of a thick solution of gum, than of proper pus, distils from the follicles. Lastly, the secretion of the sebaceous substance evidently becomes of a contagious nature in favus.

23. The formation of the epidermis is itself more or less modified in almost all the inflammations, and especially in those that are designated as *scaly*; serous or purulent fluids, following *vesicular* and *pustular* inflammations, are sometimes deposited between this membrane and the corion, or in the cavities of the follicles.

The production of the nails and hair may also present remarkable modifications, which I shall explain when treating of the morbid alterations of these structures.

24. The *absorbing* powers of the skin,<sup>4</sup> and its faculty of disengaging *gaseous fluids*,<sup>5</sup> as phenomena in health and disease, admitted by some observers and denied by others, call for further investigation.

25. GENERAL SYMPTOMS.—Every acute form of inflammation of the skin, that is intense and of some extent, is accompanied by fever, more or less violent in its character; often, too, this fever precedes the heat of surface, and even any alteration in the appearance of the integuments.

<sup>1</sup> One of the latest classifications of the diseases of the skin, is to be found in the work of the excellent and very learned writer, Dr. Craigie, entitled, Elements of General and Pathological Anatomy. 8vo., Edinburgh, 1823. It is alluded to by Dr. Rayer in the note under page 17.—R. W.

The precursory symptoms are very remarkable in certain acute inflammations, denominated eruptive fevers by a great many authors, such as rubeola, scarlatina, varicella, variola, miliaria, &c.<sup>1</sup> In these affections, the fever and general symptoms precede, by many days, the morbid appearances of the skin, which, in the interval, is neither painful nor apparently changed in its principal functions. Some authors even think that these febrile symptoms constitute such eruptive diseases much more than the eruption itself; and examples are quoted of variolous, miliary, and other fevers occurring without any eruption. This much, at least, is certain; that the general disturbance of the functions is to be taken into very particular consideration, in appreciating the phenomena of these diseases, and in adopting rules for their treatment. We also observe attacks of erysipelas and urticaria come on without any appreciable cause, after a day or two of fever. The denominations, *erysipelatos* fever, *miliary* fever, &c., used by some authors, indicate certain presumed analogies between these diseases and the eruptive fevers. The fever sometimes ceases, and always declines, with the appearance of the eruption. Several internal inflammations, and particularly anginae of different kinds, are developed in the same manner, after general febrile disturbances of the system. Lastly, several cutaneous affections are preceded by symptoms which are not febrile in their nature: these are pains more or less acute; they occur particularly in herpes zoster and herpes phlyctenodes, and often continue long after the disappearance of the eruption.

26. The time that elapses between the action of the specific causes of variola, scarlatina, rubeola, varicella, and sweating miliaria, and the appearance of the first appreciable phenomena in these diseases, has been entitled the *period of incubation*. Its duration varies with each species of disease. In chronic affections, capable of being transmitted by inoculation, the length of this period varies, not only according to the kind of disease, but also according to the individual infected. I shall have occasion to recur to this fact, when treating of scabies, favus, syphilis, &c.

27. As to the general symptoms which acute inflammations of the skin most usually present, at their acme or characteristic condition, they arise from the affection of one or more organs, and sometimes from that of a particular system according to the species, as is demonstrated by the comparative study of variola, rubeola, scarlatina, &c. The number and severity of these symptoms are not always in the ratio of the intensity of the cutaneous inflammation. This, indeed, in a vast number of cases, is but one among the elements of these diseases, and, very often, one of the very least importance.

The inverse ratio that exists between the urinary secretion and the cutaneous exhalation, is very conspicuous in some inflammations of the skin. Graefe maintains, that the particular odours which in variola and miliaria are disengaged from the skin, coincide with changes in the state of the urine.

28. Chronic inflammations of the skin often supervene without being preceded by the slightest disturbance of the principal functions. These complaints, however, often give rise to a degree of nervous irritability during the day, and to sleeplessness through the night. The irritation caused by prurigo has been seen to induce, not only sleeplessness, but even gradual emaciation of the frame and, finally, death. Several chronic inflammations of the skin, especially those that occur in the genital organs, may excite unwonted venereal desires,<sup>2</sup> and even a sort of satyriasis.<sup>3</sup> This connection of the integuments with the generative functions, observed under other circumstances,<sup>4</sup> occurs only in a very small number of cutaneous diseases.

29. *Complications*.—Other diseases,—amenorrhœa, dysmenorrhœa, &c., are occasionally combined with the invasion of acute and chronic inflammatory affections of the skin. These last may be either the effect or the cause of the first; and it is often difficult to determine which is primitive, which consecutive.

<sup>4</sup> Meibomius. *De usu flagrorum in re venerea*. Leidæ, 1629, in-12.

In a certain number of cases, both primary and secondary affections appear to be the consequence of one, and often of the same specific cause,—as in rubeola, scarlatina, &c.

When treating particularly of each form of inflammation of the skin, I shall point out the diseases that oftenest appear accidentally in its course: I may here cite, as examples of these frequent complications, that of scabies with prurigo, of ecthyma with rupia and boils, of eczema with impetigo, of scarlatina with sudamina, &c.

30. When eruptive fevers are complicated together, instead of running through their usual periods, they present remarkable peculiarities. Sometimes one of them suspends its progress, to resume it at the period of convalescence from the other, which follows its course: sometimes, on the contrary, the stages of the intervening affection appear to be accelerated. Certain eruptions are modified in their development and in their appearance, when they are contracted nearly at the same time, as has been seen in some closely approximated or simultaneous cases of inoculation of small-pox and cow-pox in the same individual.

31. To the present time, but a small number of anatomical investigations have been instituted into the diseases of which individuals, attacked with chronic inflammatory affections of the skin, have died. After death, lesions of the lungs, of the organs of digestion, of the uterus, &c., have been observed, in proportions which do not seem to differ from the relative frequency of these morbid alterations, observed under other circumstances and in other subjects. These results will have no real utility, nor ever become the basis of practical inference, until the internal lesions that coincide more frequently with such and such a form of inflammation of the skin than with such another, shall have been ascertained by the examination of an immense number of bodies. It is already ascertained that rupia and lupus often occur along with scrofula; that the impetiginous eczema of the face and hairy scalp is frequently complicated in infants with chronic inflammations of the cæcum and colon, and of the mesenteric and lymphatic glands of the abdomen; that rosacea often coincides with gastro-intestinal inflammatory diseases, &c.

32. I shall bring forward no instance of inflammations of the skin complicated with biliary, mucous, or adynamic fever, the existence of which, as a distinct morbid condition, has not been demonstrated to me by any fact: I shall give a few cases of these phlegmasiæ complicated with *dothinenteritis* or furuncular affection of the bowels, and with intermittent fever, which I have long been accustomed to separate from continued fevers.<sup>5</sup>

33. Intervening diseases may modify cutaneous eruptions in their progress, their colour, their termination, &c. Under the influence of some accidental internal irritation, an eruption that has lasted for several months is sometimes seen fading and entirely disappearing, to be slowly reproduced as soon as convalescence is established. These disappearances of the inflammatory affections of the skin as *effects*, are much more frequent than the same phenomena regarded as *causes*. A patient under my care at La Charité, for a syphilitic affection, having been attacked with pneumonia, the eruption vanished almost immediately, and as quickly showed itself again when the inflammation of the lungs was subdued.

34. Not only may disease of the skin be preceded or accompanied by various other affections, but, among the inflammations of the integuments, several are even very commonly followed by other particular diseases. These consecutive affections, extremely common, and sometimes of great severity after eruptive fevers, are very rare after chronic diseases of the skin. The distension of the veins of the face, in hypertrophy of the nose following rosacea; the baldness consequent on favus; the ugly cicatrices produced by burns; the spots and cicatrices of syphilitic spots,—are all effects of primary, and not of secondary affections.

35. Certain diseases of the skin may alternate<sup>6</sup> with alterations of

<sup>5</sup> Vide *Dict. de Médecine*, Art. *Intermittent*, t. xii.

<sup>6</sup> Novi hominem cui quoties herpes conquiescunt, loties hæmorrhoides erumpunt, largo imbre fluentes et cruciatibus distinguendi. (Lorry. *De morbis cutan.*, p. 303.) —Duo tantùm hic notare suffecerit exempla. Alterum nobilissimæ mulieris quæ scirrhoso tumore ipsum uterum depascenie laborare videbatur. At tumor ille vultu sedato per fluentium ulcerum herpeticorum sorditiem sanabatur. At tumor pessimo percussa consilio, rursus in hepate decubebat, dièndè verò in utero rursus; et eadè si ingentibus vexaretur menstrualibus hæmorrhagiis aut fluore albo mucoso per-

the viscera or of their membranes; a circumstance that has led to the belief that the former are converted into *obstructions* or *infracti-  
tions*. A young man, of twenty, had been ill for two years: at first he suffered with colicky pains and diarrhoea. The pains soon changed their seat, and settled in the stomach. From this time forward, he had great sensibility of the epigastric region, which was increased by the presence of food in the stomach; he had attacks of vomiting which, though they occurred but rarely at first, became at length so incessant, that the patient was reduced to the lowest state of marasmus and debility. After two years of suffering, and the fruitless employment of a variety of remedies, the patient came to Paris to consult Professor Bourdier. His condition was now deplorable; emaciated in the extreme, his strength gone, and the stomach unable to bear even the smallest quantity of broth. M. Bourdier learned from the patient: first, that he had had a considerable boil on the inside of the right thigh, the progress of which was very slow; 2dly, that the colic and diarrhoea had supervened shortly after the cicatrization of this boil; 3dly, that he had been relieved as often as a number of small ulcers had appeared between the toes of each foot; 4thly, that the vomiting had, on the contrary, increased when these healed up. Acting on this information, M. Bourdier ordered a blister to be put on the seat of the old boil, and flour of mustard to be placed between the toes. Twelve hours after the application of these remedies, the vomiting ceased, and the appetite had returned. The blister was kept open, and two months scarcely elapsed before the patient completely recovered.

When any internal inflammation, which has been long stationary, is accidentally increased in intensity, it often causes, or is followed by, the disappearance of cutaneous eruptions, should there happen to be any on the surface at the time.

36. *Anatomy of the Skin*.<sup>2</sup>—The human skin, when studied anatomically, from within outwards, presents, 1st. the *corion*, *dermis*, or *true skin*, the outer surface of which exhibits a vascular net-work and papillae; 2d, a deep *epidermic layer*; 3d, a *pigment*, deposited partly in this membrane, and partly in the epidermis; 4th, the *epidermis*; to these must be added the *sebaceous follicles*, the *nails*, and the *piliferous bulbs*. (a) These elementary parts and appendages

(a) To these several parts should be added, to complete the structure of the skin, the sudorific organs and their ducts, or the sudoriferous glands. They lie deeper in the substance of the dermis than the sebaceous glands, and extend more plentifully beyond into the adipose tissue. They are small, oblong bodies, composed of one or more convoluted tubule, or of a congeries of globular sacs, which open into a common efferent duct, and the latter ascends through the structure of the dermis and epidermis, to terminate by a funnel-shaped and oblique aperture or pore upon the surface of the latter. In most cases they are colourless or almost transparent. These vessels, in the number of their windings, and in their direction through the skin, vary in different parts of the body. In the right hand these spiral tubes are bent from left to right, and on the contrary direction in the left hand.

In anticipation of what may be said of the diseases of the different elements of the skin, it will be sufficient in this place to remark that our knowledge of the morbid states of the apparatus consisting of the sudoriparous glands so recently discovered, must be necessarily very restricted. So far, opportunity has not been allowed to observe positive lesions of tissue; and we can only speak of their deranged functions under the heads of augmented, diminished, and altered secretion. M. Wilson (*Diseases of the Skin*) describes augmentation of secretion under the heads of sudatoria simplex, and sudatoria maligna.

petuo, horumce malorum neutrum experiebatur. (Lorry. De morb. cutan., p. 58.)—Lorry, also, speaks of a youth, labouring under scirrhus obstruction of the spleen, and rosacea of the nose, in whom the cutaneous affection extended as often as, by appropriate remedies, the splenic tumour was lessened. Remedies, however, being laid aside, the spleen regained its former size, and the gutta rosea declined notably, both in intensity and extent.—Op. cit., p. 648.

<sup>1</sup> Bouchard. Essai sur l'emploi des derivatifs externes, &c., p. 56, in-4. Paris, 1816.

<sup>2</sup> Galen has left some remarks on the structure of the skin. The anonymous author of the *Introductio Anatomica*, and, subsequently, Avicenna, first speak of the *panniculus carnosus*. Jul. Casserius observed, that the skin was continued into the nostrils and mouth, and gave a figure of the epidermis, separated from the dermis. Fabricius Hildanus has carefully described the dependencies of the skin in man and animals. Bichat investigated, with wider views, the properties of the skin, epidermis and hair.

of the skin all undergo numerous primary or secondary alterations, in consequence of inflammation.

I shall give the anatomical characters of the exanthemata, of vesicles, of bullae or blebs, of pustules, of tubercles, &c., among the general observations placed at the head of the several orders, or whilst tracing the history of the particular species they include. I restrict myself, here, to some preliminary remarks on the degree in which the different elements of the skin are affected in the various inflammatory diseases to which it is subject.

37. In the major number of cutaneous phlegmasiæ, the *corion*, or at least its deep and fibrous layer, is but little affected. The vascular net-work and the papillae on its external surface, with the sebaceous follicles and hair-bulbs, are the seat of almost all these diseases, if we except furuncle, sty and anthrax, which are developed in the subcutaneous cellular membrane, and interstitial tissue of the corion. Pus is sometimes found in the cellules of this tissue after burns, and those chronic and intense inflammations occasioned by the application of cantharides.

Hypertrophy of the corion may be the consequence of several chronic forms of inflammation,—of lichen, of lepra, &c. This change is more particularly remarkable in Arabian elephantiasis, and the first stage of scirrhus. The corion becomes softened in some deep-seated species of cutaneous inflammation; and this alteration, which is altogether different from gangrene, precedes perforations of the skin whenever these take place.

38. The morbid injection of the vascular rete of the external surface of the corion, is the principal anatomical character of one group of cutaneous inflammatory affections—the exanthemata.—This injected state, also, occurs in a remarkable manner, beneath the epidermis when it is raised by an effusion of serum or pus, in vesicular, bullous and pustular inflammations, and even under the scales of squamous inflammations. It is no less remarkable, also, in tubercular inflammations.

The veins of the rete are sometimes permanently enlarged in old cases of rosacea, in eczema of the lower limbs of aged people, and particularly in some species of bloody nævi.

The frequency of erysipelatous inflammation of the face, has been attributed to the predominance of the rete there; but other parts, whose vascular net-work is very conspicuous, as the glans and the labia pudendi, are rarely attacked by erysipelas. The frequency of this disease in the face must, therefore, be owing to other circumstances.

39. The *papillæ*<sup>3</sup> of the outer surface of the dermis, appear to be especially affected in squamous inflammations. The papillae of the skin sometimes attain an extraordinary size on the surface of blisters

—(Anatomie générale, vol. 4, p. 640, 8vo., Paris.) Gaultier studied analytically, the elements of the skin, which can easily be followed in the integument of the neat's-tongue, and in the human skin hypertrophied (Système cutané de l'homme, 4to. Paris, 1809-1811). Blainville has given a beautiful exposition of the tegumentary apparatus, considered as an organ of defence, of absorption, of secretion, and of sensation, in the different classes of animals (Principes d'anatomie comparée, in-8. Paris, 1822).—Cours de physiologie générale et comparée, 15e et 16e livraison, in-8. Paris, 1829). Chevalier, (Lectures on the general structure of the human body, and on the anatomy and functions of the skin; 8vo. London, 1823;) C. M. André, (De cute humana externâ, Lips., 1805;) J. B. Wilbrand, (Das Hautsystem in allen seinen Verzweigungen; Giessen, 1813, in-12;) Van der Busch, (De integumentis communibus; Leidæ, in-4, 1814;) Joan. Carol. Graeffe, (De cute humana, in-4, Leip., 1824;) Langston Parker, (Mechanism of the skin, Lond. Med. Gaz., vol. vii., p. 353;) and W. Wood. (an Essay on the structure and functions of the skin, 8vo., Edin., 1832;) have made many interesting remarks on the structure and functions of the skin. Schroeter has endeavoured to represent its texture (Das menschliche Gefühl-Organ des Getastes, etc. folio, Leip., 1814). Voigtel (Handbuch der pathologischen Anatomie; 8vo., Halle, 1804; 1st. Band, p. 65), has made some remarks on the alterations of the dermis, of the epidermis, of the sub-cutaneous adipose layer, and of the follicles. Craigie (Elements of general and pathological anatomy, 8vo., Edinb., 1828), has added several anatomical observations on classification. Lastly, to Gendrin (Histoire anatomique des inflammations, in-8., Paris, 1826, t. i., Anat. path. de la peau enflammée, p. 397), we owe many interesting investigations on several forms of inflammation of the skin.

<sup>3</sup> The papillæ discovered by Malpighi, (De Lingua, exercit. in Epist.—De externo tactus organo in Epist. Op. Omn., t. ii.) have been admitted and described by Ruysch, who has figured those of the nipple of the female, of the teat of the whale, and of the tongue of man, (Thesaurus, anat. ii., tab. iv., fig. 1, 4, 6, 7, 8, 9,) by Albinus, (Acad. annot., lib. iii., cap. ix. et xii.) by Hintze, (De papillis cutis tactui inservientibus, Lugd. Bat., 1747,) by Gaultier, (Rech. anat. sur l'organisation de la peau de l'homme, in-4, Paris, 1811,) and by Dutrochet in his Observations sur la structure et la régénération des plumes, avec des considérations sur la composition de la peau des animaux vertébrés. (Journ. de phys., Mai, 1819.—Journ. compl. des sc. méd., t. v., p. 366.)

that have been long kept in a state of suppuration; but this is above all in the Arabian elephantiasis, in syphilitic affections accompanied with morbid growths, in some naevi, in ichthyosis, and in one variety especially of this disease observed in individuals who have been designated *porcupine men*, that the elongation of the papilla becomes so remarkably conspicuous. Some pathologists have supposed that prurigo was caused by inflammation of the papillæ; but this assumption has not been supported by any anatomical facts. The disease occurs most commonly on the outer parts of the thighs or arms, and on the shoulders, situations in which the eye does not detect numerous papillæ, and is never seen attacking the cushions of the fingers, heels, toes, or where they are very conspicuous.

40. The *deep-seated epidermic layer* (*couche albide profonde*, Gaultier), which cannot usually be perceived in the human skin, I have seen very distinctly in some cases of Arabian elephantiasis. It is precisely like the external epidermis. I am not aware whether it undergoes any modification in other cutaneous affections or not.

41. The *pigment or rete-mucosum*<sup>1</sup> is altered in the greater number of cutaneous inflammations; for a certain quantity of blood is almost always deposited beneath the epidermis, in the epidermic layer of the papillæ when it exists, on the surface, or in the substance of the dermis; even the exanthemata sometimes exhibit these bloody suffusions. From the quantity of blood deposited, and the amount of its elements imbibed by the skin, result spots or stains of a brown, livid, coppery, or yellowish-gray colour, &c., which continue for a longer or shorter space of time according to the age and the constitution of the individual affected, the nature of the disease, and the means of cure employed.

42. The *epidermis*<sup>2</sup> undergoes numerous alterations at the decline or during the course of many inflammations of the skin; it becomes dry and brittle, and then it chaps and splits, or is detached from the true skin in the form of bran, scales, or plates, and sometimes in large flaps from regions where it is thicker or stronger, as it is on the soles of the feet, the palms of the hands, the knees, the elbows, &c. Its detachment is rarely followed by the fall of the nails, but most commonly by that of the hair.

The colour of the epidermis may undergo several modifications.—It grows yellowish in some syphilitic affections, black in one variety of pityriasis, of a dull white in lepra, and of a pearly hue in some pityriases of the hairy scalp. The increase or diminution in the thickness, in the transparency, and in the tenacity of the epidermis all furnish important characters in the determination of species.

43. The *sebaceous follicles*<sup>3</sup> are attacked by diseases peculiar to themselves.<sup>4</sup> They become altered in many affections which were primarily unconnected with them. The parts of the skin most frequently inflamed are also those that are most amply provided with follicles. The history of eczema, of impetigo, of favus, of acne, of rosacea, &c., demonstrates how frequently inflammations of the follicles occur, and how various these diseases are in their characters. The follicles of the chin in man are subject to a very intractable species of pustular inflammation—*syccosis menti*. The follicles of the pubes are more rarely affected than those of any other region of the body.

<sup>4</sup> C. Kæstel. De folliculorum sebaceorum morbis, in-8. Rostock, 1828.

44. The alterations of the *hair-follicles* or *bulbs* will be last described. To the diseases generally known to affect these minute organs, favus must be added.

The hair-bulbs of the genital parts and axillæ are more rarely diseased than those of the face and scalp. In the axilla, especially, the hair-follicles are deeper and larger than anywhere else, and their inflammations are always more than usually severe and rebellious in their nature.

45. I shall, by and by, describe those alterations which the *nails* experience when the skin which they cover is attacked by lepra, eczema, psoriasis, syphilis, &c.

46. The relative frequency with which cutaneous inflammations occur on the right and on the left side of the body, is a subject which, if not very useful, is at least curious. When I treat of zona, icterus, &c., I shall present the remarks of Mehlis on this subject,<sup>5</sup> and point out certain errors into which he has fallen, his calculations not having been made on data sufficiently extensive.

47. Some forms of inflammation are set up indiscriminately on every part of the surface:—such are erythema, ecthyma, and others; but many of the same class of maladies affect certain regions especially: eczema shows itself on the hairy scalp, on the ears, and on the margin of the anus; prurigo affects, in preference, the outer parts of the limbs; lupus attacks the cheeks and alæ of the nose; rosacea, syccosis, and acne, regarded as modifications of the same disease, invade the face, the chin, and the integuments of the trunk; others, again, constantly occupy the whole, or almost the whole, surface of the body at once; such are measles, scarlatina, &c.

48. The *etiology* or doctrine of the causes of cutaneous inflammation, has been the subject of much research. The *roots*, to use an old and characteristic expression, of certain local diseases of the skin, such as warts, follicular tumours, horny appendages, &c., were distinguished at a very early period to be internal. To approach as nearly as possible to a true knowledge of the causes of cutaneous disease in general, it has been found necessary to study not only the nature and the effects of external stimuli on the skin, but, further, the relations of the skin to the principal organs of the economy,<sup>6</sup> and the influence of diseases on affections of the integuments.

49. Thus studied and compared in their causes, their progress, their termination, their treatment, and their nature or mode of existence, inflammations of the skin fall naturally under two categories. Those of the one, essentially local, and produced by external evident causes, are easily and promptly cured; those of the other, developed without any appreciable outward cause, appear linked to morbid states of the system,—to more or less complex conditions of the organization, of which they are only, so to speak, symptomatic expressions; thus we say *scrofulous lupus*, *purpura hemorrhagica*, &c.

50. Natural excretions, or other matters, deposited on the surface of the skin,—the scurf of the hairy scalp, in pityriasis capitis, for example, the matter of the perspiration in intertrigo aurium, the mucous discharge in the same disease of the thighs, the contact and friction of the dress, garters, corsets, &c.,<sup>7</sup> and a multitude of irritating substances, such as mustard, cantharides, tartrate of antimony, Bui-gundy pitch, croton oil, &c., excite particular inflammations, which appear under various forms,—exanthematous, vesicular, or pustular.

51. Many chronic inflammations are caused by want of cleanliness. It was partly to this cause that Willan attributed the great number of cutaneous diseases, observed in London, among the lower classes of society. The frequency of skin complaints, or of itch, at least, among the inhabitants of lower Brittany, is due to the state of filth in which they live, and to the ease with which this disease is communicated. It seems certain that prurigo, and several artificial forms of inflammation, would be less common among the poorer classes, were they not compelled, by necessity, to neglect the use of baths and other similar means of preserving health, which their laborious occupations often render more particularly necessary.

<sup>7</sup> Sauvages numerat *crispelas* in cute nascens a collarium ecclesiasticorum uso. (Lorry. De morbis cutan., p. 6\*)

The subject of *cosmetics*,<sup>1</sup> their uses and abuses, &c., ought to be resumed in another spirit, and presented in a more scientific shape, and in better keeping with the present state of knowledge, than has hitherto been done.

52. *Too high a temperature* of the atmosphere is the evident cause of several forms of inflammation of the skin; the eczema solare, and lichen tropicus, may be cited as examples. The same cause often aggravates chronic inflammations, such as rosacea and lichen facialis, or increases the itching occasioned by some others, as lichen simplex, scabies, &c. Moisture and cold combined, cause a particular inflammation of the skin of the hands and feet, called chilblain.

Exposure to cold hastens the formation of the wheals in urticaria, and favours the development of the Arabian elephantiasis in Egypt and Barbadoes.

53. The influence of electricity is little known; all we are certain of is that the electric spark will produce indelible stains of the skin.

54. Certain inflammations occasionally act as direct causes of some others. It is thus that small-pox and measles cause the development of the boils and ethyma so often observed in convalescence from these diseases.

55. Many particular modifications and affections of the digestive functions exert an influence, badly defined indeed, and certainly exaggerated, yet established by incontestable facts, on the development of certain diseases of the skin.<sup>2</sup> Who has not seen the brow, nose, cheeks and eyelids of young people, habitually temperate, become covered with spots and pimples, after two or three days of indulgence in the pleasures of the table? Let but habitual irregularity of life follow such accidental excesses, and a chronic inflammation of some sort will almost certainly be established in the face or some other region of the body. It is also known that drunkards are so much the more subject to gutta rosea, as their favourite beverage is more strongly charged with spirit.

56. The influence of salted and highly seasoned food on the development of chronic inflammation of the skin, has long been known, and never disputed. Rice, oysters, mussels, lobsters, shrimps, &c., and different kinds of fish, sometimes also cause exanthematous eruptions.<sup>3</sup>

57. Lorry has mentioned a similar effect produced by certain medicines. "Every time," says he, "that I have had occasion to prescribe acrid or volatile spirits (esprits âcres ou volatiles) to some of my patients, small itchy non-critical rashes, occasionally containing serum, have come out on their skin." I have, myself, seen eruptions produced by the essential oil of turpentine, by cubeb, pepper, belladonna, &c. Fourcroy gives, as one of the signs of poisoning by nitric acid, an eruption of pustules analogous to those of the small-pox. Hemlock taken into the stomach sometimes causes stains of the skin, especially of the legs and thighs.

The process of dentition in children often gives rise to the development of erythema and strophulus, vulgarly called tooth or teething rashes. Lastly, many cutaneous inflammations are preceded by inappetence, bitter taste of the mouth, nausea, sometimes by actual vomiting, and other functional disorders of the digestive organs.

58. From Galen downwards, a great number of writers have regarded the major part of the chronic affections of the integuments as *bilious*.<sup>4</sup> The frequency of skin diseases in infancy, seemed to be

explained by the remarkable development of the liver. Pujol quotes the case of a dropsical old maid, who had suffered from obstruction of this organ during ten years, and to which there succeeded a humid and crusted tetter on the thighs and arms. A sister-in-law of Pujol, who was attacked with a humid tetter of the ears, suffered afterwards from an hepatic affection. Lieutaud assures us anatomical investigation has satisfied him that obstinate eruptions of the skin, as well as other chronic diseases, have often been owing to some derangement of the liver; Lorry maintains that altered bile produces pruriginous pustules, carbuncles, &c.: lastly, according to Pujol, we are to conclude that a disease of the skin depends on a change of the bile, whenever the malady has come on in a bilious subject without evident cause, or when it has been preceded by the suppression of an hemorrhoidal flux, by a bilious fever, by jaundice, by hepatic colic, by obstinate intermittent fever, or when it has originated under the prolonged influence of a stimulating or heating regimen. Darwin holds that acne is connected with derangement of the primæ viæ; and Mr. Plumbe has grouped together several diseases which he conceives to be generally symptomatic of a deranged condition of the digestive organs. Barbette has, with good reason, denied that the liver and the bile exert so great an influence on the production of chronic inflammation of the skin: and, in fact, I have myself, repeatedly, seen not only diseases of the biliary apparatus without any eruption on the surface of the body, but in a multitude of cases of cutaneous affections, I have found it impossible, with all my care, to discover any trace either of antecedent or concomitant lesion of the liver or of the parts connected with it. Lastly, in warm countries, where disorders of the biliary apparatus are so frequent, the coincidence of diseases of the skin with affections of the liver, has never been particularly dwelt upon by authors.

59. A few imperfectly recorded cases have also led some to believe that diseases of the spleen were occasionally reflected upon the integuments.<sup>5</sup> The results of my own researches, more numerous and more conclusive than those of Valli, are at variance with this assertion.

60. In individuals attacked with chronic inflammation of the skin, the digestive apparatus is very commonly perfectly healthy; and were it even shown that affections of the stomach, of the liver, or of the spleen, were generally found accompanying skin complaints, it would not be, on that account, quite fair to infer that the latter were symptomatic of the former, for they might both be effects of the same cause.

To conclude this subject, then, it is undeniable that certain articles of food and of medicine taken into the stomach, and some gastrointestinal affections, do cause eruptions of various kinds on the skin: but it is not less certain, that the Galenists of old, and, in later days, the disciples of the physiological school,<sup>6</sup> have exaggerated the importance of these causes; the former in attributing to changes in the bile, the latter to irritation in the stomach and bowels, results over which it is impossible to prove that the biliary or digestive apparatus habitually exercises any influence.

61. A great number of cutaneous inflammations may be produced by mental labour, by excessive watching, by rooted sorrow or by any other act or circumstance that modifies the state of the nervous system.<sup>7</sup> The misery and gloom that pervade the northern parts of Italy, have been assigned as a cause of the pellagra so common there. Of five hundred insane patients in the hospital at Milan, Dr. Holland reckoned that two-thirds were affected with pellagra. Numerous cases of meladermia, eczema, zona, pemphigus, erysipelas, and urticaria, which I have collected, prove that the influence of the nervous sys-

<sup>7</sup> Cum inter aquæ purissimæ potores viderim non unum qui dilutâ stomachali saburrâ, sese pustulis ad frontem indignabatur inter vini immoderatos bibaces recenseri, quorum in numero juniorem monachum studiis deditum, meri potu sanatum vidi: medicumque nimio perè meditationi indulgentem, qui aquâ ardorem laboribus innatum temperare dum studebat, faciem fœdis pustulis deturpatam habebat, hunc remissis studiis, et meri potu nitorem cutis recuperasse vidi. (Lorry. De morb. cutaneis, p. 64.)

tem on the development of these diseases is incontestable. It is well known that the insane are very subject to cutaneous eruptions and to erysipelas.

62. The influence of very energetic *muscular exertions*<sup>1</sup> on the development of diseases of the skin, has been observed by Lorry. A state of habitual rest and inaction is often accompanied by great beauty and whiteness of skin; and I have ascertained the beneficial influence which is possessed by the relaxation of the muscular system on the progress of diseases of the skin among the labourers and handicraftsmen received into our hospital.

63. The opinion very generally diffused among persons labouring under chronic affections of the skin, of their diseases being kept up by some alterations of the blood,<sup>2</sup> by some morbid state of the humours, is strengthened by sundry observations. I have noticed that the blood was buffy in a great many of these cases, even when there was no fever, and no appreciable disorder in any of the principal functions. In anthraxion or malignant pustule, in small-pox and measles, the blood is certainly charged with some principle of contagion. Pujol assures us that the serum of the blood is bilious in several cutaneous diseases. It is very probable that certain agents only exert their influence on the integuments after having been carried into the torrent of the circulation. The inflammation of the skin in the mercurial disease, and the leaden hue that follows the long-continued internal use of the nitrate of silver, are examples of the effects of such absorptions. As to the *alterations of the lymph*, and the *acrimony of the serum*, the *mucus* and the *humours*, which used to be universally admitted, almost all that has been written and taught on the subject, is hypothetical. I except those experiments that have been made on the contagious qualities of the fluids or matters of cow-pox, small-pox, scabies, of the nasal mucus in measles, &c. The appearance of many of these affections without appreciable cause, their hereditary properties, their frequent recurrence and so forth, are so many circumstances which the alteration of the blood, were it demonstrated, would render less obscure.

64. The state of *general plethora*, observed in individuals of a sanguine temperament, whose skin is habitually ruddy, is more rarely the cause of cutaneous inflammation than the *local plethora*, produced by the stasis, or habitual or accidental allux of a certain quantity of blood to any particular region of the surface of the body.

65. The relations between the skin and the organs of respiration, have been well observed by Meckel.<sup>3</sup> Our knowledge, however, of the influence exerted by diseases of the organs of respiration on those of the skin, is confined to a very scanty number of facts. Alibert has related two cases of eczema alternating with paroxysms of asthma. Hooping-cough is known to be occasionally followed by cutaneous eruptions, and phthisis often causes exhausting epidrosis, and occasionally severe sudamina.

66. I have seen some chronic inflammations of the skin appearing only during pregnancy, such as eczema impetiginodes and prurigo, and others ceasing, or at all events, declining sensibly in their violence during menstruation, pregnancy and nursing. In these cases, however, the diseases showed themselves anew on occasion of the suppression of the menses, or at the natural period of the cessation of this flux. I have observed eczema, and other chronic inflammations of the skin unexpectedly invading females who had been compelled by the death of their child or nursing, to give up nursing suddenly; these are the *milk eruptions* (*dartres lacteuses*) of certain writers. Similar cases have long been familiar in practice.<sup>4</sup>

67. Some authors tell us that the abuse of the sexual propensity may induce eruptions on the skin: (a) Lorry thinks they are more fre-

quently the effect of an opposite cause. "Certè," says he, "utriusque sexús evolutione factâ, si castam instituerint vitam erumpit vulgo ingens pustularum conglomerata congeries." Young girls who suffer from these eruptions, and particularly from acne, are very often attacked with rosacea at a later period of life.

68. Lorry informs us that pruriginous eruptions are sometimes seen to break out in individuals attacked with nephritis.<sup>5</sup> Although my attention has been particularly turned to diseases of the kidneys for some years, I have not met with any case confirmatory of this assertion.

69. Not only do certain *diatheses* modify the characters of some cutaneous diseases, but they eminently predispose to the development of several of them. I have observed that scrofulous children, with thick lips, and heads of the shape of a calabash, were often affected with eczema impetiginodes of the face and hairy scalp, during the course of the first dentition. They are sometimes attacked with phagedenic affections (*dartres rongeantes*) of a very obstinate character, at the age of seven years, and about the period of puberty.

70. Among the causes of skin diseases, Galen mentions the *arthritic virus*; Ludwig<sup>6</sup> points to the same source, and Lorry tells us that in families where the gout was hereditary, those individuals who escaped the disease, were subject to tettery eruptions. Pouteau, also, speaks of the influence of rheumatism in the development of cutaneous diseases. I am, myself, satisfied of the frequent alliance of diseases of the skin (*dartres*) with gout and rheumatism; I have seen these affections disappear suddenly, without any obvious cause, and the patients become the victims of the most violent pains in the articulations.

71. The hereditary nature of a great number of diseases, and particularly of many cutaneous affections, is one of the best established facts in pathology. It often follows the law of resemblance, and sometimes that of sex.

72. Some individuals, free from hereditary diseases, and apparently of a good constitution, are yet so subject to certain kinds of cutaneous inflammation, that Hufeland<sup>8</sup> has seen fit to designate this condition by the title of *Constitutio psorica*, a denomination for which Jos. Frank has substituted that of *Constitutio impetiginosa*. I have myself given my advice to a great many persons in whom eczema, psoriasis, lichen, &c., appeared to be the effect of a constitutional predisposition which was very difficult of removal, and which tended continually to recur, independently of any accidental or other appreciable cause.

73. Several inflammatory affections of the skin may be congenital (erysipelas, variola, pemphigus); others appear especially in infancy (strophulus, pemphigus *infantil*, roseola *infantil*, measles, favus, &c.), and others again are more commonly met with in old age (prurigo *senilis*, pemphigus *pruriginosus*, and so forth.)

74. According to Alibert, scavengers, and those who live habitually in air loaded with sulphurous vapours, are rarely affected with chronic inflammations of the skin.<sup>9</sup> Some have also fancied that workers in charcoal, and those employed in preparing plumbago or black-lead were cured of the cutaneous diseases with which they happened to become affected, by the mere influence of their occupations. I have myself met with too many exceptions to these notions to have any doubts of their inaccuracy. Artificial vesicular and papular eruptions have been described under the name of *grocer's itch*, and *baker's itch*, which are either the consequences of local stimulants, or true eczemas happening in persons exercising these trades. Hydrargyria has been observed among the labourers in quicksilver mines. The trades that demand great muscular exertion and require the person to be exposed to high temperatures, render those that exercise them liable to sudden relapses of such complaints as eczema, lichen, rosacea, &c., a few days after apparent recovery from these affections.

(a) They are a common effect of masturbation.

<sup>1</sup> Undè qui nimio motui, præsertim antè ætatem maturam indulgent, vultu varicoso et pustulosâ facie incedunt notabiles, si præsertim latet intus acre superfluum (Lorry. De morb. cutan., p. 43).

75. The influences of *local situation*, of *climate* and of *season*, more remarkable than those exerted by *trades* or *professions*, cause varieties in cutaneous affections which call for attention, and so modify the bodily organization, as to render it more obnoxious, or less liable to be attacked by one or another of these diseases. A multitude of denominations, such as pemphigus of *India*, of the *Brazils*, and of *Switzerland*; tropical lichen, lepra of the *Arabians*, lepra of the *Greeks*, and lepra of the *Jews*; sweating disease of *Picardy*; malignant pustule of *Burgundy* and *Persian* fire; summer roseola, autumnal roseola, &c., show that this influence had been noted, and, perhaps, even exaggerated by pathologists. Several diseases are, indeed, observed almost exclusively in certain countries—pellagra in the Milanese, the Aleppo pustule in Syria, plica in Poland, and so on.

It would be both a curious and an interesting subject of investigation to determine the relative degrees of frequency of inflammatory affections of the skin, and of their different species according to *climate* and *local situation*. Observations on this subject at the present time are too scanty to form the basis of any comparative inquiry of the least importance.<sup>1</sup> The most contradictory conclusions would evidently follow from inquiries commenced with insufficient data.

76. With this study of the influence of local situation and climate, that of *endemic* cutaneous affections, such as sweating miliaria, anthracion or malignant pustule, plica, pellagra, &c., is naturally connected. I have myself proved that sweating miliaria was endemic in moist and shady places: and statistical accounts of several other diseases of the skin have been begun, and ought by all means to be continued.

77. As to those cutaneous diseases which were formerly epidemical, but which are now no longer so, such as Greek elephantiasis in the middle ages, and syphilitic affections towards the end of the 15th and the beginning of the 16th centuries, their mode of attack and the causes of their evolution, are as unknown to us as those of the small-pox, measles, scarlatina and other epidemics which we, in our own day, see attacking communities at frequently recurring intervals. It is impossible to say why some diseases, after having had the epidemic character at one time, should have lost it at another, whilst certain others have constantly preserved this feature.

78. The history of *medical constitutions*, as regards inflammatory affections of the skin, is exceedingly incomplete. It seems demonstrated, however, that erysipelas frequently requires particular methods of treatment according to the prevailing epidemic constitution; that roseola, rubeola, scarlatina, &c., have occasionally a character of mildness, or of malignancy, which becomes a distinguishing feature in different epidemic invasions of these diseases. It is wrong to question the accuracy of these circumstances; but it is no less erroneous to attempt to see throughout each year, and even each quarter of the year, a common character in the cause and progress, of many diseases that are essentially different; and it is with less reason still, that only one mode of treatment for the whole of these various affections has been recommended.

79. Several acute inflammations (variola, vaccinia, &c.), and some chronic forms of skin disease (scabies, favus, &c.), are contagious. These affections are transmitted by means of particular agents, known under the name of virus, miasm, &c. The human subject is in general only once affected with small-pox, measles, and scarlet fever. But one attack of scabies, of favus, or of syphilis does not give security against a second. Scabies, which is especially contagious by contact, cannot be communicated by inoculation; the vaccine pock, transmissible by inoculation, is not so by simple contact, nor by its matter being rubbed upon the skin. The number of diseases of the skin, capable of being transmitted by one or other of these modes of contagion, is not yet satisfactorily ascertained.<sup>2</sup> "I once saw,"

says Pujol, "a dentist labouring under a violent eruption (eczema?), of the right hand, infect, in one day, the faces of a great number of pupils in the royal military school of Sôreze. The eruption appeared on the faces of the boys four or five days after the contact of the dentist's hand."

80. *Diagnosis.* Inflammatory affections of the skin, generally considered, are distinct from hemorrhagic affections of the same tissue. In these last, the attendant redness does not disappear on pressure, neither is it accompanied by heat, and it is most commonly free from all morbid sensations. Moreover, desquamation of the cuticle or some accidental secretion is an almost invariable consequence of inflammation; neither of which circumstances is perceived in hemorrhagic affections, the red spots of these passing successively through shades of a greenish and brightish yellow as they disappear.

Whenever there is a production of squamæ or of furfuræ, or any accidental secretion, inflammation is no longer liable to be confounded with simple congestion. There is never any real difficulty except when the point to be determined is, whether certain congestions with morbid heat, sometimes observed after violent emotions of the mind, or at the period of menstruation in women in whom this function is performed with difficulty, are the first appearances of an erysipelas or not. And we observe in fact, that if the congestion but continue, inflammation will very speedily take its place.

81. The determination of species seldom presents any serious difficulty when the disease possesses its essential characters, when it has reached its acme, or has passed through one or more of its stages.

Various acute inflammations, and eruptive fevers in particular, sometimes exhibit, on their invasion, none but equivocal characters, —nothing beyond general and ill-defined disturbance: at a later period, and towards their decline, these diseases only exhibit features more or less modified, and occasionally so much altered, that these afford us no assistance in our diagnosis, unless compared and contrasted with antecedent phenomena.

In a given case, it is necessary first to inquire what the cause of the disease may have been; then, by attentive examination, to ascertain the form to which the eruption belongs; that is to say, whether it be exanthematous, bullous, vesicular, pustular, and so on. There remains no more to be done but to compare the symptoms and the progress of the species under review, with those of the phlegmasiæ, which present themselves under the same generic aspect.

82. The diagnosis may be rendered difficult in a greater or less degree, according as the primitive form of the inflammation remains unchanged or is much altered, as it is destroyed or replaced by new and consecutive alterations; lastly, as the disease is simple, or complicated with other inflammations of the skin of the same, or of different elementary forms. An attentive examination of consecutive alterations (scabs, ulcers, scales, cicatrices), sometimes of itself, and without any other hint, leads to a knowledge of the nature of the primary lesions, which are, moreover, often to be discovered with all their peculiar characters in the immediate vicinity of those points of the skin which were first affected. When it happens that several forms are conjoined in the same situation, or in the same individual, there is always found one predominating, to which the others, determined by way of analysis, must be attached as adventitious, and be held as constituting *complications*.

83. Inflammatory affections of the skin being sometimes associated with diseases of the mucous membranes of the viscera, or of the parts connected with them, the presence or absence of such affections, together with the apparent causes of their origin, require to be noted in order to render the diagnosis complete.

84. *Prognosis.* There are no grounds upon which the prognosis can be founded save a precise knowledge of the natural progress and terminations of acute and chronic inflammations of the skin, the degree of efficacy of the means employed in their treatment, the circumstances that may hasten and complete, or that may oppose and prevent their cure, such as the appearance of the menstrual flux in young women arrived at puberty, its near cessation in females who are approaching the critical period, &c.

In the majority of acute characteristic inflammatory affections, especially in simple eruptive fevers, the advance, the periods, the phenomena, the duration of the disease,—all may be calculated and

<sup>1</sup> Willan and Bateman on the diseases of the skin in London. (Willan. Reports on diseases in London, in-12, 1801.—Bateman. Reports on the diseases of London, in-8. London, 1819.)—On diseases of the skin in Dublin. (Med. and Surg. Journ., Edinb., xxxiv., p. 99.)—Segond. Maladies de la peau à Cayenne (Journ. hebdomadaire, t. iv., p. 434).—According to Lorry: "Obnoxii sunt morbis cutaneis, Britones, Picardi, Flandri, Batavi." (De morb. cut., p. 34.) M. Richerand, on the contrary, thinks that the Dutch (Bataves) are very subject to diseases of the urinary organs, and suffer but rarely from affections of the skin.—Nouv. élém. de physiol., 10e ed. Paris, 1833, tom. ii., p. 152.

<sup>2</sup> Adams. Observations on morbid poisons, chronic and acute, 4to. London, 1807.

predicted with the greatest certainty; in acute inflammations, however, of an anomalous character, and complicated with other affections of a more or less serious nature, there is no longer any rule for their progress, nor elements existing for the calculation of their issues.

85. Our prognosis must also be modified according to the age of the subject. In old people chronic inflammations of the skin that are independent of external causes ought often to be respected; they may sometimes be moderated, they ought seldom to be cured. In those of adult age, less reserve is necessary, and the prognosis is more favourable. In childhood, the greater number of chronic inflammations of the skin, except favus, lupus, and the itch, run their course, and get well spontaneously, after a longer or shorter lapse of time; at this period of life, skin complaints appear often to be the very reverse of prejudicial.

86. As to hereditary affections, those especially that depend on the scrofulous or arthritic diathesis, are necessarily obstinate and more difficult to cure than the same diseases occurring under other circumstances.

Every form of artificial inflammation whatever is easily, speedily, and often spontaneously cured.

87. Acute and chronic inflammations of the skin are sometimes salutary. The appearance of an exanthematous eruption may put an end to angina,<sup>1</sup> and abdominal infarctions (*engorgements*), to pulmonary inflammations, and wandering pains; many diseases of the skin itself have been seen arrested and cured by an attack of erysipelas.<sup>2</sup> This form of exanthema, occurring on the thorax of a woman attacked with very severe puerperal peritonitis, caused the cessation of this serious disease. I have often remarked an eruption of furuncles in adults, and of eczema impetiginodes in children, happen at the time all the symptoms of an internal inflammatory affection disappeared. I have also seen eruptions of ecthyma occur during convalescence from several acute diseases. Boils are often critical in insanity.<sup>3</sup> Pujol has seen hypochondria vanish with the appearance of furfuraceous eruptions over the whole body. A child of a year old, after having exhibited all the symptoms of meningitis, sank into coma, the sutures separated, and the head became deformed. Dr. Gall, who saw this infant, decided that she had hydrocephalus, and pronounced an unfavourable prognosis. Derivatives to the intestinal canal had been unavailing; the size of the head was increasing; the child was pale and weak; the extremities were infiltrated, when a general scabby eruption appeared, and decided its fate; the fever ceased; the colour, which had been that of yellow wax, came again, and the child by degrees recovered a state of perfect health.<sup>4</sup> The head, though still somewhat misshapen, is much less disproportioned than it was. The child, now ten years of age, is robust, and possessed of all the physical powers of the strongest children at this age; but the intellect appears to be extremely moderate. P. Frank quotes a case of inflammation of the brain, favourably terminated by an attack of erysipelas.<sup>5</sup> Rosen and Mead give instances of intermitting fevers cured by the appearance of small-pox. Prof. Andral cites a case of very severe, and almost desperate pneumonia, the symptoms of which vanished as by enchantment on the appearance of a variolous eruption. M. Brachet has seen a case of phthisis arrested by the intervention of small-pox.<sup>6</sup> I have myself seen, in the person of a young magistrate, a bronchial affection, which I regarded as complicated with tubercles, happily terminate after the spontaneous eruption of an eczema on both forearms. A mass of observations on the good effects of the vaccine pustule in a great number of diseases has been laid before the public; and whilst it must be allowed that these results are not without a tinge of exaggeration, it appears certain that this eruption has several times proved the means of giving a favourable modification to the progress of certain chronic affections. It is on this account that every form of cutaneous inflammation supervening in the course, or during the decline of an internal disease, ought, in general, to be respected, if

not too intense, and if the internal malady advance towards its termination, or become less severe in proportion as the disease of the integuments increases in extent, or runs through its periods.

88. The utility of those *artificial inflammations*<sup>7</sup> which the practitioner is every day in the habit of exciting and keeping up, over certain regions of the body, is based on these and similar observations; they were successfully employed by Fournet in angina (faucium?), by Goodwin, in angina pectoris, by Jenner, in various forms of pulmonary catarrh, and there is, perhaps, no affection, either acute or chronic, in which I have not myself tried them with various measures of advantage.

89. Analogous observations have led others to inoculate scabies, and other contagious diseases of the skin.<sup>8</sup> Dr. Lhomme recovered a child which had fallen into a state of emaciation, after an attack of enteritis, by inoculating it with *tinea*. In such cases it has always appeared to me preferable to have recourse to some artificial eruption, than to the inoculation of a disease disgusting in itself, and very often difficult of cure.

90. In other circumstances, far from being salutary, the occurrence of any form of cutaneous inflammation is prejudicial. Measles sometimes hasten the progress of tubercles of the lungs; repeated attacks of erysipelas aggravate the Arabian elephantiasis; eczema of the legs induces the ulceration of varices, &c. There are cases again in which it is impossible to determine whether an eruption shall be advantageous or hurtful. M. Calmeil, who has paid particular attention to the development of diseases of the skin among the insane, was unable to come to any conclusion in regard to the measure in which he conceived they might prove beneficial, or the contrary.<sup>9</sup>

91. The repulsion of acute inflammations of the skin is more commonly attended by grave consequences in measles and scarlet fever than in any of the other eruptive diseases. Not only is it necessary for us to be on our guard against the fatal effects of such retrocessions of these eruptive fevers, but farther to provide against those which proceed from the sudden disappearance of certain chronic inflammations, as of lichen, eczema, and impetigo. I shall have occasion to quote instances, in illustration, in regard to each of these diseases.

92. The number of cases that have been witnessed, in which the disappearance of cutaneous affections coincided with the development, or accelerated progress of an internal inflammatory disease, have made many afraid to attempt their treatment, or to desire their cure.<sup>10</sup> When there exists at the same time, in the same individual, two affections, one of which is internal, the other external, it seems improper to attempt to combat the latter by any active means.

In academical collections, instances may be found recorded of diseases of the digestive organs following the disappearance of tetter or tincas (*dartres* ou *teignes*). These cases, however, rarely occur, and seem often little conclusive. The numerous inquiries that have been instituted in later times in regard to diseases of the stomach, of the intestinal canal, and of the parts connected with these, have added but little to the earlier observations we possess; their causes have too frequently been overlooked, or passed by in silence. Nevertheless, the case related by M. Bouchard deserved to be quoted (35.).

93. Several cases tend to show that the suppression of an eruption or of a scabies may occasion epilepsy,<sup>11</sup> insanity, and other cerebral affections. In the year 1785, at Bassenheim, on the left bank of the Rhine, a corporal, about 21 years of age, of a spare and bilious temperament, labouring under a severe tettery affection (*une dartre vive*), about four inches in diameter, situated on the fore and upper part of the right thigh, was received into hospital. The disease extended over a small part of the scrotum, and caused violent itching

there. M. Bouillaud, chief surgeon of the hospital, employed a palliative and cautious treatment in the first instance; but, by and by, yielding to the importunities of the patient, who complained of the intolerable pruritus of the affected part which prevented all sleep, he gave his consent to the application of compresses, dipped in vinegar and water, to the seat of the disease. His surprise was great when the next day he found this man in a deplorable condition. The eruption had disappeared from the limb, but a state of somnolence, attended with stertorous breathing and complete absence of sensation and voluntary motion, supervened immediately afterwards. Every means was tried to bring back the disease; blisters were applied to the spot first affected, and measures calculated to subdue this apoplectic metastasis were exhausted in vain. The cerebral disease continued to advance unchecked, and the patient died on the third day. No examination was made of the body.<sup>1</sup>

Amaurosis<sup>2</sup> and convulsions,<sup>3</sup> especially in young children, have also sometimes been produced by the suppression of acute or chronic inflammatory affections of the skin. It is very possible, certainly, that effects have been ascribed to the repercussion of skin diseases, of which they were totally innocent; but when such accidents occur, as in the preceding case, almost simultaneously with the disappearance of the skin disease, they give rise to serious questions of pathology and therapeutics.

Pulmonary consumption has been seen following the cure of herpetic affections.<sup>4</sup> Lentin, Loder, Pederit and Portal have given cases of phthisis which were ascribed to the suppression of the perspiration from the soles of the feet. A young man whom I had cured of an eczema of the legs, was attacked almost immediately after with a pleurisy, for which he put himself anew under my care, and from which he was relieved without any return of the eruption. I have seen bronchitis follow the cure of rupia in a scrofulous subject; and I have collected several analogous instances of pulmonary inflammations following the methodic cure of eczema, of various species of lichen and of psoriasis.

95. Diseases of the heart and of its membrane,<sup>5</sup> have also been observed to follow the suppression of various forms of cutaneous inflammation.

96. Admitting always that these facts are deserving of much attention, I yet affirm that the mischiefs attributed to the removal of *tettors* and *lineas* (*dartres et teignes*) are much rarer than is generally imagined. The most common consequences of these retrocessions observed are ophthalmic affections, inflammations of the glands of the neck, otitis, deafness, and now and then hydrocephalus acutus in infancy; pulmonary catarrh, phthisis and other affections of the thoracic viscera in young people; affections of the liver, ascites, cystitis, &c., in riper years, and in old age. The following case is an instance as rare as it is curious of these metastases.

A wine merchant consulted M. Petit for a discharge from the urethra, which had made its appearance some days before. The pain he suffered was severe; the matter discharged was precisely similar to that of gonorrhœa, so that Petit thought he had to do with this disease in fact, but the patient declared on his honour that he had run no risk of infection, and that his wife was in the enjoyment of perfect health. It was requisite, however, to find some cause for the appearance of this inflammation; and Petit discovered it when he learned that the patient had for a long time laboured under an eruption on the skin of the fore arm, which had suddenly disappeared a few days before the discharge came on. Petit ordered the application of a blister to the place where the eruption had previously existed, and all the symptoms of the presumed clap speedily disappeared.<sup>6</sup>

97. *Treatment.* An infinity of remedies and of different curative plans have been recommended in acute and chronic inflammatory affections of the skin, in a manner so general as to render the study

of their principal applications, from the same point of view, a subject of positive utility. This first glance will also recall to our notice certain therapeutical investigations, which it would be well to repeat at the present day, and under better ascertained conditions. Farther on in this work, in the history of each particular inflammatory affection of the skin, I shall hold myself bound to specify the doses and mode of administering the remedies proper for them at their different periods, and the modifications that may require to be introduced into the remedial plan, when the causes of the disease, the constitution of the patient, and the influence of any accidental or intervening lesion, are ascertained.

98. *Treatment of the acute inflammatory affections.* There are a certain number of acute inflammations of the skin, the conditions of whose existence are such that nothing can advantageously arrest their progress; the various phenomena that accompany these diseases are as little to be opposed as the natural actions of the economy. The part of the physician is then to regulate the evolution of the disease, and to endeavour to limit its effects.

This expectant method is applicable to simple erysipelas, to common measles, to uncomplicated scarlatina, and to all artificial inflammations of little intensity. With a few exceptions it ought also to be regarded as the proper method of treatment in all cases of unmixed eruptive fevers.

Thus, therefore, many acute inflammations are to be confined within moderate bounds by regimen—by abstinence and diluents: the disease exhausts itself, and the cure is accomplished naturally. But whenever these inflammatory affections appear inclined to spread to a large extent of the surface, to invade the subcutaneous cellular tissue, or other organs, or when they are accompanied by very violent febrile symptoms, we are to interpose, by means more or less energetic, according to circumstances,—provided always that no critical phenomenon proclaims these diseases as having a natural tendency to a speedy termination. It must not be overlooked, moreover, that these inflammations have most commonly a certain number of periods to pass through, and that we cannot, without danger to our patient, seek to cut them short at their outset.

99. The degree of warmth<sup>7</sup> proper to be kept up in the chambers of patients and around affected parts, is a point upon which we are often consulted in the treatment of acute inflammations of the skin, and especially in that of eruptive fevers. In measles, a somewhat elevated temperature has appeared to me, in general, advantageous. This would be very painful, and probably very prejudicial in scarlatina. It would add to the swelling and to the headache in erysipelas of the face.

100. The febrile symptoms accompanying acute and uncommunicable inflammations of the skin, are moderated by the abstraction of a quantity of blood, when the constitution of the patient admits of the practice; the progress of the eruption is then milder and more regular. I must, however, again remark, that there are a number of cases in which the spontaneous and natural termination of the diseases is so evident an event that it is well to abstain entirely from bleeding, which in this case would have the effect of needlessly reducing and weakening the patient. Of late, the local abstraction of blood has certainly been abused in the treatment of eruptive fevers. Recalling an erroneous opinion of M. La Mettrie, it has even been proposed to *cut them short* by means of repeated bleedings. This mistake pointed out, it must still be allowed that the abstraction of blood is imperatively called for in the treatment of those intervening inflammations which the disappearance of eruptions often gives rise to. Experience has amply confirmed, in my own hands, the advantages of this practice approved and established of old.<sup>8</sup>

Local bleedings are generally useful in phlegmonous erysipelas, in scarlatina anginosa, in variola accompanied with obstinate vomiting, in measles complicated with intense bronchitis, or with pneumonia. In children this mode of abstracting blood requires particular care; without it the bleeding is seldom effected in due measure, being almost always either insufficient or excessive; leech bites in them bleed either too little or too much.

<sup>6</sup> Bouchard. *Essai sur l'emploi des dérivatifs externes*, p. 56, 4to. Paris, 1816.

101. When the eruption in fevers is either small in quantity or disappears improperly, Pujol informs us that it can be excited or brought back by the tartarized antimony exhibited in emetic doses, and the patient thus rescued from great jeopardy. In certain epidermic constitutions, *emetics* have been recommended as preferable to the expectant method and to blood-letting.<sup>1</sup> Generally recommended by P. Frank and Cullen in the beginning of acute diseases in which the skin appears more or less affected with inflammation, tartrate of antimony is at the present time confined in its application to a smaller number of cases. Often useful in erysipelas, owing to an outward cause, in urticaria occasioned by eating muscles, &c., tartrate of antimony and ipecacuanha have been too generally prescribed in the commencement of measles to favour the throwing out of the eruption, which may be impeded by morbid conditions of the most dissimilar kinds, such as convulsions, pneumonia, difficult dentition, &c. &c. Lastly, according to M. Fontaneilles,<sup>2</sup> a solution of a drachm of the tartrate of antimony to a pound of water, by way of fomentation, is an excellent antiphlogistic in erysipelas and various other acute cutaneous phlegmasia.

102. Purgatives, recommended with justice by Hamilton in scarlatina, are no less beneficial in hydrargyria, and in some cases of variola, of erysipelas, and other diseases. Halle informs us that several bold or rather rash attempts have proved that small-pox might sometimes yield through all its stages to the evacuating plan of treatment. I have not myself repeated this experiment.

103. *Diaphoretic drinks*,<sup>3</sup> particularly tepid infusions of borage and of sambucus nigra, may generally be advantageously prescribed to allay the thirst of the patients and determine to the skin during the two first periods of the eruptive fevers. Recourse is also sometimes had to the tepid bath in the treatment of phlegmonous erysipelas of the limbs, of ecchyma, of papular erythema, of the small-pox, &c. The same means are sometimes employed with a view to recall the eruption in measles when it has disappeared suddenly. The vapour bath is occasionally used with similar intentions.

104. *Liniments* of cream, of oil, or of grease diminish the heat and dryness of the skin in erysipelas, variola, and scarlatina; those of cream give great relief in the confluent small-pox of the face.

105. Wright, Currie, Martius, and others, conceive that the reaction which follows the affusion of cold water over the surface of the body, is often useful in certain cases of scarlatina and rubeola, attended with a dry and burning heat of the skin, or with a tendency to meningitis. I have never tried this method, against which there prevails a general prejudice in France.

Cold water, plain or acidulated, has been used with success as a lotion or a bath in the treatment of burns of various degrees of intensity, as also of ulcers, and in cases where the skin has been affected with heat and itching. Water in abundance as a diluent has been extolled by Hancock and many others in the treatment as well of general fever as of scarlatina, measles, and small-pox.

106. Harris relates several instances of the good effects of the application of *alcohol* in erysipelas;<sup>4</sup> *ether* is also sometimes used to burns; and James<sup>5</sup> tells us he has often tested the efficacy of this remedy in the painful inflammation that occasionally follows the use of blisters.

107. *Urtication*, or stinging with nettles has been imagined to restore the eruption of fevers, in which it had receded too rapidly. I have often replaced this means by the use of sinapisms, and of mustard baths in the cases of children.

108. *Blisters* are often successfully used to fix erysipelas of an erratic nature, to bring the inflammation to the exterior in phlegmonous erysipelas, and to restore it in case of its retrocession in eruptive fevers. Stoll<sup>7</sup> conceives that their application, in miliary fevers,

ought to be preceded by the use of purgatives; a precept which seems too general.

109. The *nitrate of silver* in substance or in a concentrated solution, has of late been recommended as a cautery to check the progress of certain acute diseases of the skin, and to prevent the mischiefs that sometimes complicate them. This plan which has been styled the *ectrotic* has been put in practice in the case of small-pox, of erysipelas of the face, of zona, and of several other varieties of herpes.

110. Experiments to a certain extent demonstrate that *mercurial preparations* do really exercise a remarkable influence over the evolution of acute cutaneous inflammations. Recommended in erysipelas by M. Ricord, they had previously been used as preservatives against variola and scarlatina. According to Wedekind, small-pox pustules are not evolved in those situations that have been covered with a mercurial plaster, and the effects of inoculation are prevented by washing the punctures with a solution of corrosive sublimate and sal ammoniac.

Dessessart has extolled *calomel* as giving immunity from small-pox.<sup>8</sup> Sacco and Selig say that mercury destroys the specific properties of vaccine matter, and weakens or interrupts the progress of the pustule already formed. Hoffman, Baglivi, Lettsom, Lentin, Andry, Reil, Hufeland, Hildebrandt, Cotugno, and others have pushed mercury to salivation in the very beginning of small-pox, in order to mitigate its violence. Huxham, Bailey, Douglas, Kreysig, Hufeland and others have also recommended it in this disease, and Loesecke, Mueller, and Hamilton have reaped great advantages from the medicine in measles. I have repeated several of their experiments, and in the proper place will make known the results of my inquiries.

111. As to *preservative methods*, I can only quote the efficacy of the vaccine pustule against small-pox, and the demonstrated usefulness of belladonna in epidemic scarlet fever. The property ascribed to camphor of destroying the infection of measles is much less than certain. Intermittent erythema and urticaria are to be treated like febrile accessions. As to *periodic inflammations* dependent on amenorrhœa, on dysmenorrhœa, or the suppression of an habitual evacuation, their recurrence is prevented by reinstating these evacuations or finding substitutes for them in blood-letting, and the use of purgatives.

112. *Treatment of chronic inflammations.* The treatment of chronic diseases of the skin is held with justice to be one of the most difficult matters in the healing art. Besides getting occasionally well under the influence of the most dissimilar remedies, the choice and application, and occasion to make use of which are beset with numerous difficulties and much uncertainty, we cannot conceal from ourselves something of a secret disinclination to attack many of these affections, the disappearance of which may be succeeded by more or less serious symptoms.

113. Vegetable diet, white meats, &c., are available in a great many chronic inflammations of the skin appearing in young subjects, or in people of mature years, but of sound constitutions. A sober and regular life, habitual cleanliness, a diet composed of white meats, fresh vegetables, and ripe and watery fruits, contribute essentially to the effects of the therapeutic agents employed. Living on white meats (*diète blanche*), fish, chicken, &c., has been held by some as the only efficient remedy against chronic inflammations of the skin.

*Milk diet*<sup>9</sup> perseveringly employed, has accomplished cures where pharmaceutical preparations, directed with the best views, had totally failed. This regimen, however, is injurious to elderly people; under its influence I have seen several fall into a state of anemia, which a recurrence to more nutritious food caused to disappear.

Some individuals digest milk with difficulty; almost all, however, at length become accustomed to it, as Pujol well observes. The stomach is sometimes brought to bear this article of diet by the use from time to time of lime water. Some digest asses' milk more readily than any other; some again find goats' milk, either alone or mixed with barely-water, sit most lightly on their stomachs.

114. Veal or chicken broth may be recommended to those who have a distaste to the habitual use of milk; particular advantages have been presumed, by some, to be possessed by broths made from the

<sup>9</sup> "Lac in omnibus cutaneorum morborum curationibus adeo celebre est, ut multi illi soli rite applicato omnem omnino fiduciam addant, reliquis neglectis, si pro solo victu eo utantur." (Lorry, de morb. cul., p. 339.)

sea-turtle, from the lizard<sup>1</sup> and the viper;<sup>2</sup> and the numerous cases detailed of their good effects in Italy, Germany, France and England in cases of cancer, lepra, elephantiasis, syphilitic eruptions, &c., should induce us without prejudice to repeat these experiments.

115. *Fasting*, or the use of a quantity of food less than the appetite demands (*cura famis*), has been recommended in various forms of chronic inflammation of the skin, and particularly in syphilitic affections. I have myself often obtained great and permanent advantages by reducing the quantity and changing the quality of the aliment. Lorry gives instances of this kind.<sup>3</sup> But few patients have the firmness to restrict themselves to a severe regimen and to endure the privations it implies. Females submit more readily than males. A celebrated *accoucheuse* of Paris, otherwise of a good constitution, suffered under a *phagedenic tetter* of the cheeks; she gave up her usual mode of living which was very nutritious and *recherché*, and confined herself to vegetables dressed with a small quantity of butter and seasoned with salt: she recovered, and ten years afterwards had had no relapse.

Under the influence of these severe fasts, the constitution is so much weakened, that though the skin diseases get well, the strict regimen has often to be abandoned; and then the eruptions reappear, in the same measure as the general health improves under the stimulus of better diet.

116. Circumstances depending on age, on temperament, on anterior or concomitant affections, and on the particular situations in which patients are placed, sometimes require the tonic and *strengthening plan* to be substituted for the fasting and the antiphlogistic treatment, which, however, is generally much more extensively applicable.—See particularly under the heads *rupia*, *lupus* and *impetigo*.

117. If the advantages of an appropriate regimen are well proved, the mischiefs arising from imprudences and irregularities in the mode of living, from the abuse of coffee,<sup>4</sup> of strong drink, of salt and highly-seasoned food, &c., are not less apparent. It is enough, in a great number of cases, for patients in the way of recovery, or actually well, to abandon for a moment the strict system they had followed, to suffer an increase or a recurrence of their disease. Sometimes, too, these relapses happen after such an interval as seemed to warrant some remission of the severe watch that had been previously kept over the kinds and quantities of food employed.

118. *Rest*, and the absence or diminution of muscular exertion of every kind, have a marked influence on the progress of chronic inflammations of the skin. I have seen individuals attacked with severe psoriasis, completely cured by remaining patiently for a month in bed; and the effects of the same endurance are not less remarkable upon eczema and impetigo. A plan of life the very opposite of this—hardship and fatigue—has been recommended by Van Swieten against syphilis. The results of my own experience are not favourable to this counsel, as I have always seen active exertion of body aggravate syphilitic affections and impede their cure.

119. Daily observation demonstrates the utility of *external remedies* in the treatment of chronic inflammations of the skin. The ancients often made use of them, but it was almost always only after the exhibition of one or two cathartics. Lorry has restricted their employment to too narrow a circle, and repudiated a number of topical applications of undeniable worth. Bell again has extolled them too highly; because, if the necessity of acting directly on the organ affected be demonstrated in a great number of cases, it must also be owned that in a multitude of chronic inflammations of the skin

(eczema, lichen, lupus, psoriasis, lepra, pityriasis, Greek elephantiasis, &c.), the local affection of the integuments is nothing more than one of the conditions of the disease, and that recoveries after simple local treatment are commonly incomplete.

120. Some external remedies, such as the acids, the nitrate of silver, actual cautery, &c., have a mere local effect, whilst the others are followed quickly or at a later period by phenomena which result from the absorption of the substances applied to the surface of the body. The salivation that follows the inunction of mercury; the emaciation observed after the protracted use of iodated baths or unguents; the increase of muscular strength from the sulphureous bath; the colic and paralysis that result from the application of the salts of lead to abraded surfaces; the pains of the bladder, occasioned by blisters, &c.; bear witness to these secondary effects, and to their importance.

121. When we reflect that so many diseases of the skin are owing to the neglect of proper cleanliness, and that the greater number are accompanied with an increased heat of surface, or by morbid secretions, we cannot be surprised at the excellent effects obtained from the use of *simple baths*, whether as soothing inflammation actually existing, or preventing its return. The advantages of baths of the decoction of bran, of emollient, gelatinous and oily baths, and those prepared with starch, marsh-mallows and lettuce, are no less evident. These are all preferable to the ordinary tepid bath. We know that fish-glue, and the glue prepared from bullocks' hides, in the isle of Rhodes, were used dissolved in water by the old Greeks in the treatment of burns, psoriasis, ecthyma, &c. These gelatinous baths ought in general to be administered at a very moderate degree of heat, as prolonged and repeated hot baths are rarely endurable when the skin is in a high state of inflammation.

122. *Cold baths*, and bathing in running streams in particular, are serviceable in a great number of chronic inflammations, which from their nature, their form, or their long continuance, have become fixed to particular places. I have made a number of experiments on the administration of *narcotic cold baths* in the treatment of chronic and painful inflammations of the integuments, the results of which were highly satisfactory to me.

123. *Soothing fomentations*, such as those prepared with decoction of marsh-mallows, of althea, of the *acanthus spurius*, of lactuca sativa, of beet root, of the herb pellitory, and other mucilaginous plants, as also those esteemed of a sedative nature, that are prepared with poppy-heads, with elder-flowers, with olibanum, with melilotus officinalis, with euphrasia, veronica chamaedris, the leaves and stems of the plantago, &c.; likewise cataplasms of crum of bread, rice flour, potato starch, &c., applied of a gentle warmth to circumscribed inflamed surfaces are generally useful.

124. By *anointing* the body with oil, or grease of any kind, the skin is made softer and more pliant, and pain, heat and itching are sometimes allayed. It was long thought that each variety of greasy substance employed had peculiar curative virtues, and M. Chevreul<sup>5</sup> has, in fact, ascertained that these bodies not only vary in the relative amounts of their constituent elements, but also by the presence or absence of certain accessory principles, which possibly may be not without influence in a therapeutic point of view. If lard be more generally employed than any thing else, it is only on account of the readiness with which it is everywhere to be procured.

Hufeland<sup>6</sup> has recommended frictions with olive oil, or with nut oil in tetter (*dartre*). Linseed oil is familiarly used in the treatment of burns; and Delpech has proposed the employment of oils generally in scabies.

125. The advantages of *blood-letting* are less obvious in chronic than in active inflammatory diseases of the skin. Yet general as well as local bleedings by means of leeches and cupping-glasses have, under my own eyes, had the happiest effects in many chronic cases. I have derived the greatest advantage from this practice in eczema, impetigo of the face and hairy scalp, psoriasis, lichen, local prurigo, herpes phlyctenodes and other forms of chronic affection. It is generally proper to repeat the local abstraction of blood in young

subjects as often as the inflammation shows a disposition to extend, or is attended with considerable pain. I have even put this practice in force in the cases of elderly people of hale constitutions, with great advantage.

126. The *preparations of sulphur* have long and deservedly enjoyed an extensive reputation in the treatment of chronic diseases of the skin, and especially of scabies.

*Sulphureous waters* taken internally during one or several seasons modify the constitution materially, and perhaps accomplish a greater number of cures than any other means. In France, the natural sulphureous mineral waters of Aix (Provence), of Bagnères,<sup>1</sup> of Bagnères de Luchon, of Billazai (Deux Sèvres), of Barèges,<sup>2</sup> of Cauterets, of Enghien, of Gréoulx (Basses Alpes), of Bagnols (Loire), of Aix (Ariège), and of Saint Amand (Nord), are justly celebrated; in Germany, those of Aix-la-Chapelle, of Wisbaden, and of Nenndorf; those of Aix and of Saint Gervais, in Savoy; of Baden, of Lapeyrière, of Schinznack, and of Louèche, in Switzerland;<sup>3</sup> of Guitra (Corsica), of Argui, in Piedmont; of Alhama, and of Hardeles in Spain; those of Naples; those of Baden (Lower Austria), of Baden (Swabia); those of Harrowgate, Leamington and Bath, in England, are also very salutary. After having been drunk for several days, some of these waters, particularly those of Louèche, occasion a particular eruption, characterized by small acuminated and itchy spots, and red blotches which appear first on the limbs, but, by and by, extend over nearly the whole surface of the body: a febrile paroxysm, accompanied by anorexia and great thirst sets in, the sleep is disturbed, and the urine is turbid and high coloured. All these symptoms abate within eight or ten days in the order of their appearance; the epidermis is thrown off in flakes, and the pruritus is soon the only symptom that remains for some little time longer. This eruption appears to be one evidence of the beneficial operation of the waters, and ought not to cause a suspension of their use. The baths of Baden (Argovie), the waters and baths of Saint Amand sometimes, but by no means so generally, occasion symptoms analogous to those produced by the waters of Louèche.

There are many other mineral waters found over the face of different countries of Europe which are also familiarly used internally in skin complaints.

127. I have had ample opportunity at La Charité and elsewhere of satisfying myself of the virtues of *artificial sulphureous baths*; but to secure their good effects, it is certainly necessary to regulate the *temperature* and the *duration* of these baths, not only by their manifest effects on the skin, but by their influence on the constitution. In a very great number of cases I have found that there were immense advantages to be derived from gradually increasing the time of remaining in the bath to the amount of even five or six hours. This practice, so commonly followed at the natural springs, is by no means to be neglected in our establishments of artificial mineral waters, as some have proposed. I have attended children who have been brought to remain in the bath during three whole hours; and adults and persons further advanced in life, have at length been induced to stay four or five hours without exhaustion in the artificial sulphureous-water bath. The chief obstacle to this practice arises from the patients themselves, who, living in large towns and not duly appreciating its importance, will rarely consent to sacrifice so many hours to the care of their health. It is by this means, nevertheless, that those constitutions which make individuals subject to skin complaints are most certainly modified, and that the relapses so frequent after every mode of treatment, are most surely prevented.

128. The *hot air bath* and *dry sulphureous fumigations*, tried in the treatment of skin complaints by Glauber<sup>4</sup> and Lalouette,<sup>5</sup> and brought forward anew with convenient modifications by M. Galès,<sup>6</sup> are now

rendered easily and safely applicable by means of the improved apparatus of M. Darcet.<sup>7</sup> Messrs. Clarke<sup>8</sup> and Wallace<sup>9</sup> have severally published interesting remarks on their effects, which to me, however, seem to be not without a tinge of exaggeration. The same thing may be said of the observations of Decarro, of Vienna.<sup>10</sup> Sulphureous fumigations are undeniably often serviceable in chronic eczema, but they are rarely available against pityriasis, lepra and impetigo. They certainly weaken the patients more than sulphureous-water baths; they also modify the constitution in a less durable manner, and more rarely accomplish perfect cures. These fumigations, too, sometimes irritate the skin further; they have been known to occasion syncope, a sense of suffocation, &c. It would be imprudent to attempt their use without great discretion among children, pregnant women, asthmatic persons, or in cases where there was any suspicion of tubercles in the lungs.

The *vapour of sulphur* administered by the process of M. Balland is much less irritating than fumigations with sulphureous acid gas, in lieu of which it may often be substituted with advantage.

*Lotions and ointments of sulphur* have the same effects as the baths; their activity may be increased by the addition of different substances; such as iodine and mercury, which are more or less energetic in their actions, or diminished by others that seem to have little or no sensible effect on the economy, such as charcoal and sulphuret of antimony. These tropical applications do not modify the constitution, and are generally less useful than the prolonged employment of sulphureous-water baths.

129. The *sulphuret of potassa, of soda, and of lime* are made use of, not only for the composition of artificial baths, but in solution internally, in the dose of five or six grains to the pint of water as a drink, or in the same quantity mixed with some vegetable extract. Pure sulphur is also prescribed internally in the dose of from twelve to twenty grains, especially by the vulgar, as a purgative, or in the idea that it may be absorbed and thus affect the constitution generally.

130. Baths of sea-water, cold or hot,<sup>11</sup> and those of the mother-waters of our salt-mines<sup>12</sup> are very efficacious in many forms of chronic inflammation of the skin, especially in serofulous subjects. Russel advises the internal use of sea-water before beginning to bathe. Lind has recommended sea-water in scabies and obstinate forms of ulceration. M. Delaporte has treated a great number of individuals affected with scabies by means of sea-water baths, and M. Zompitoute<sup>13</sup> has combined their action with that of the sulphuret of potassa, a method that deserves recommendation, especially in the cases of sailors and of soldiers quartered in seaports during the heats of summer.

I have myself seen very obstinate diseases of the skin, and particularly chronic eczemas of the verge of the anus, which had resisted arsenical preparations, get permanently well after one or two seasons of sea-bathing. Should the disease return, the sea-bathing must be resumed the following summer, until the cure seems established. This practice is said to be very generally followed in the hospital at Newcastle; and we may soon expect to be in possession of valuable reports on this interesting point of therapeutics, which has not yet been sufficiently attended to, from the physicians to the establishments for sea-bathing which have been formed in France at Dieppe, Boulogne, Havre, and Rochelle. It is of some importance also to point out those cases in which sea-bathing is contra-indicated, as well as those in which it proves advantageous. I have thought that it was prejudicial in spare and irritable temperaments. In very extensive skin affections, and in squamous inflammations, it is generally well to advise a few tepid baths, before entering on those of cold water. It is seldom that sea-bathing, as a remedial means, is employed alone; it is generally combined with some internal treatment, which, of course, always enters for something in any result obtained.

131. At Paris, *artificial alkaline baths*, which approximate, in a certain degree, in their composition to those of sea-water, are prescribed under similar circumstances. These are prepared in the hospitals by dissolving from four to six ounces of the subcarbonate of soda, in an ordinary tepid bath. Common culinary salt sprinkled on the surface of cutaneous eruptions, has been recommended by Schelling.<sup>1</sup> The salt-water contained within oysters, is a vulgar remedy for ulcers of the leg; and I know a patient who succeeded in getting rid of a very disagreeable eczema *podicis*, by employing this water as a lotion.

[The brine of salt-meat is another popular remedy, in England, against various forms of skin disease.]

132. Baths of *saline, natural mineral-waters*, have also been occasionally employed in affections of the skin, the species of which, however, have not been particularly described.

133. *Soap lotions*, formerly much recommended in skin diseases, are still generally used as a means of cleanliness, and have lately been advised by M. Lugol, in cases of scabies.

134. *Local baths*—(manuluvia—pediluvia—hip-bath)—have been prescribed, not only as topical applications, but with a view to promote the absorption of various medicinal substances. Foot-baths containing corrosive sublimate or nitro-muriatic acid, have been tried in several eruptive diseases, and in syphilitic affections, but with very variously-reported effects.

135. *Saliva*, which is spoken of by Galen and Celsus,<sup>2</sup> is still a popular application to the scales of pityriasis, and to lichen of the face. Nurses often employ their spittle to allay the violent itching which children suffer who are attacked with strophulus.

136. The *urine*, especially that first passed in the morning—*urina sanguinis*—was an ancient remedy, and is still used by the vulgar, when they are attacked with itch, *pediculi*, and chronic eczema of the hairy scalp.

137. General and partial *vapour baths*<sup>3</sup> may be of service in restoring to the exterior certain inflammations of the skin that have receded, in the removal of squamæ and of scabs, in exciting the circulation in those regions of the skin to which they are particularly applied, and in stimulating inflammatory affections of an indolent nature. They are further usually employed under a great variety of circumstances which I shall be careful to expose in their proper places. P. Frank even tells us that the vapour which exhales from the body of an animal just killed, has proved a remedy in certain cases of cutaneous disease.<sup>4</sup>

138. Several chronic forms of inflammation of the skin have been successfully treated by *iodine and its compounds*.<sup>5</sup> This medicine has been particularly recommended in cutaneous affections occurring in scrofulous constitutions. I have seen good effects from the combination of iodine with mercury, sulphur, and opium in scrofulous lupus, and in tubercular and ulcerated syphilitic affections. These compound remedies, as their action is very energetic, require to be carefully watched. Like all the preparations of iodine, they have a very marked effect on the constitution.

*Externally*, an ointment or pomatum of iodine and of the proto-ioduret of mercury, as also solutions of iodine of various degrees of strength, general or local iodated baths, iodated cataplasms, caustic iodine (a solution of an ounce of iodine and an ounce of ioduret of potassium in two ounces of water), &c., have all been employed by M. Lugol and others, in the treatment of scrofulous lupus (*scrophules esthiomènes*) and of some other cutaneous affections. I have myself particularly tried the action of the iodurets of mercury and of sulphur.

*Internally*, the *iodated mineral water*, prepared according to the formula of M. Lugol, appears to me the best of all the forms devised for the exhibition of iodine. The medicine may also be prescribed in the solid state in gradually increasing doses of half a grain, three-quarters of a grain, one grain, one grain and a quarter daily. I shall have occasion to revert to the effects of this active remedy under the heads *lupus* and *syphilitic affections*.

139. *Styptics and astringents* to the skin have been strangely abused by quackery. Lorry cites a serious instance of their ill effects.<sup>6</sup> He is, nevertheless, of opinion that the cure of old and obstinate cutaneous affections having been once obtained, it is proper to endeavour to give tone to the affected parts of the skin by the use of various styptics, such as washes of the acetate of lead, acidulated baths, solutions of aldm, &c.; and it is undeniable that this practice, much extolled by Bell, is often advantageous. The ill effects of the *salts and oxides of lead* have been greatly exaggerated.<sup>7</sup> These preparations are often useful in allaying certain inflammations of the skin, accompanied by morbid secretions. *Preparations of zinc*<sup>8</sup> are used under similar circumstances, and with the same views.

140. The *sulphate of alumina*<sup>9</sup> in solution as a wash, in the proportion of an ounce, or an ounce and a half of the salt to a pint of water, lessens the morbid secretions of the skin in eczema fluens, lichen agrius, &c., and greatly relieves the itching that accompanies these diseases. This means, recommended by Turner, is not duly appreciated by Lorry. *Borax*<sup>10</sup> has also been employed externally, united with hog's-lard and alum, in the treatment of pityriasis and several other chronic inflammations of the skin.

The sub-acetate of copper, or verdigris, besides a multitude of other preparations of this metal,<sup>11</sup> have long been familiarly used as external applications in cutaneous affections, especially in those of a syphilitic nature.

141. *Lotions and fomentations of simple cold water* may be advantageously employed in a number of cases to diminish uneasy sensations of heat and itching.

*Compression*<sup>12</sup> recommended by Bell, and particularly by Baynton in the treatment of ulcers, by Bretonneau in phlegmonous erysipelas of the legs, and by Velpeau in cases of severe burns, has been tried in eczema, scirrhus tubercles, nævi, and Arabian elephantiasis. The situation and disposition of parts may sometimes render compression difficult or painful, and as it does not attack the conditions that lead to the formation of cutaneous diseases, it is generally to be regarded as a remedy of secondary importance.<sup>13</sup>

142. *Charcoal*<sup>14</sup> has been tried internally and externally as a remedy in scabies, which may be cured more certainly and easily by other means. Thomann obtained the cure of tinea in three cases, in the space of from three to five days, by the use of charcoal in powder, and soapy lotions. M. Brache did not succeed by the same means in less than a month. According to Hunold, charcoal made into a paste with rum is a popular remedy in various skin complaints in the city of New York. The trials I have myself made with charcoal, either alone or combined with sulphur, have satisfied me that it is of no use in favus, and that the other affections of the hairy scalp yield

more readily to other remedies. The application of charcoal in powder to the ulcers that follow rupia, lupus, &c., powerfully stimulates the ulcerated surfaces, and greatly increases the quantity of discharge.

The workers in charcoal told M. Poissant, a practitioner at Brest, that they always escaped scabies and tetter (*la gale et les dartres*). Lampadius gives some cases of inflammatory affections of the skin cured by the carburet of sulphur.

143. The *oxide of manganese*,<sup>1</sup> in powder, has been used outwardly as an absorbent in the treatment of old ulcers; combined with various substances as a *depilatory*; and along with one or two parts of lard, as an application to different eruptions of the skin and scalp, with better effect, it is said, when these diseases had advanced to a state of ulceration, than when they were simply scaly or miliary. The workmen employed in the mine of manganese<sup>2</sup> at Macon, are said not to be subject to itch; and the people in the neighbourhood, attacked with this disease, seek a remedy by labouring at the works for a time.<sup>3</sup> The oxide in pills, and even by way of gargle in the same, and also in syphilitic affections, has been recommended by Dr. Kapp of Bareuth.

The *muriate of manganese* has been prescribed, in various cutaneous affections, in the dose of from one to twenty grains daily; but I have not made trial of the medicine myself.

144. Several inflammatory diseases of the skin, primarily of a chronic nature, or become so, often remain long stationary; circumstances in which local stimulants are had resource to with advantage. The practice is followed by a temporary exasperation of the symptoms, after which complete recovery sometimes follows. In the use of these means we are to beware of exceeding certain limits; for by pushing them too far the disease may be aggravated, and made to assume a more serious character than it had originally.

145. *Lime*, united with an equal quantity of soap, is used to destroy small tumours, warts, excrescences, and *nævi*. Hufeland,<sup>4</sup> in cases of tinea, recommends a mixture of equal parts of olive oil and of lime. Lime appears to be the basis of a quack depilatory powder employed in France with success in favus. Combined with sulphur and some fatty body, lime also forms a pomatum of the same character, often employed in various forms of skin disease, particularly in scabies. It must not be forgotten that when used externally, either by itself or mixed with oil, lime sometimes stimulates too much, or otherwise causes the too rapid disappearance of cutaneous eruptions. Internally the hydrochlorate of lime (*muriate of lime*) has been recommended in cases of scrofula, lupus and elephantiasis.

146. The *liquor ammonia* properly weakened has been recommended to check the spreading of the inflammation in burns. Lotions of this preparation, and various salves into which ammonia enters have been long used in different cutaneous affections, with what advantage is doubtful.

147. *Acid lotions*, and liniments with various proportions of different concentrated acids have been recommended in the treatment of such chronic inflammations of the skin as impetigo, rosacea, prurigo, &c.

*Acetic acid* diluted with water, of old recommended in lepra and lichen,<sup>5</sup> has been recently brought again into notice in these diseases by Mr. Wilkinson.

*Sulphuric acid*<sup>6</sup> has been used externally as a cautery or as a stimulus to certain chronic inflammations of the skin. *Nitric acid*<sup>7</sup> combined with lard forms an ointment that has been greatly vaunted by Alyon. In a state of purity it is employed to cauterize various eruptions, or to destroy the surface of foul and ill-conditioned ulcers; diluted with water it forms an excellent wash to many sores of the same description. The *hydrochloric* (*muriatic*) *acid* diluted with water favours the recovery

of frost-bitten parts; made into an ointment with lard, or united with some fixed oil, it has been prescribed in tinea, various scaly eruptions, and scabies. The medicinal *hydrocyanic acid* in the proportion of one part to two of spirit and twenty of water, has been found by Dr. A. T. Thomson to allay the pain and irritation of impetigo.<sup>8</sup> Dr. Schneider, of Dusseldorf, has derived great benefit from the use of a drachm and a half of hydrocyanic acid, added to six ounces of spirit and as much rose-water, in many scaly affections attended with severe itching, and especially in those eruptions upon the genital organs that often prove so troublesome. These prescriptions I have myself tried, and by and by shall have occasion to refer to the results.

148. Deimann and Van der Bosch have celebrated *chlorine* applied externally in some skin diseases,<sup>9</sup> and Dr. Kapp has reported new instances of its successful use in cases where there appeared an excess of plastic power. Duncan has recommended in tinea and some ulcerated states of the skin, the application of an oil through which a current of chlorine has been passed. Chlorine has also been tried in scabies, and the *Pharmacopée universelle* gives a recipe for a *pommade antipsorique* or itch ointment composed of a drachm of chlorine and an ounce of hog's lard.

149. The *chlorate of soda* was used by Alibert in lupus (*dartres rongeantes*) and by Roche in a case of tinea favosa (*porrigo lupinosa*, Willan) which had resisted other remedies.<sup>10</sup> We have also reports of three cases of eczema of the hairy scalp (*tinea mucosa*) treated by the same means, in the work of Chevallier,<sup>11</sup> who has given the formula of a *pommade* composed of chlorate of lime and turpeth mineral, which was found beneficial in a case of obstinate tetter (*dartre rebelle*.) According to M. Derheims<sup>12</sup> scabies may be cured in from six to ten days by a dilute solution of the chlorate of potassa, soda, or lime, or better by the same compounds prepared directly and containing an excess of chlorine. Prurigo of the female labia and various irritable stages of the vagina yield readily to lotions with the chlorate of soda.<sup>13</sup> I have further to add, that I have myself experimental proof of the usefulness of the chlorates in the treatment of a great number of chronic diseases of the skin.

150. Experience has taught us that the *nitrate of silver*<sup>14</sup> may often be employed advantageously as a superficial cautery to the skin, when affected with obstinate chronic inflammation; but it is also known that this active substance, prematurely employed, may be followed by an aggravation of the symptoms it was intended to counteract, and that when indiscreetly applied, it has sometimes caused great alteration in the texture of the integuments, and given rise to indelible cicatrices.

151. M. A. Severinus<sup>15</sup> had recourse, in several cases of lupus, to the *actual cautery*, which had been previously employed by Albucasis in the same formidable malady. Saucerotte details the case of a little girl attacked by an ulcer consequent upon a burn, which he remedied by exposure to the powerful rays of the sun.

152. It is very long since proposals were made to change chronic into acute inflammations of the skin, and thus by modifying their nature and accelerating their progress, more speedily to bring about their cure. It was with this view that Hippocrates<sup>16</sup> added cantharides to the ointment called *karikon*, which was used to dress certain ulcers. Celsus<sup>17</sup> also treated severe papulæ by an ointment of cantharides.

Galen<sup>1</sup> advises us to excite suppuration in points of the skin affected by obstinate disease (lupus, mentagra), by means of a mixture of cantharides and hellebore, incorporated with grease and a variety of other articles. Paulus Ægineta, and particularly Aetius, have advised the same practice, which was revived by Paré<sup>2</sup> when, upon the recommendation of Hollerius, he ordered a blister to be applied to the face of a woman affected with rosacea. Several other pathologists have had recourse to applications of cantharides in lepra, lupus, and psoriasis. Lorry was witness to the same disturbing means successfully resorted to by a quack. I have myself had frequent and successful recourse to it; but I have always preferred ordering repeated small blisters, to the application of a single large one, where there was a considerable extent of diseased integument to be treated. It is proper to remember, that the patient of Paré suffered a violent fit of delirium.

M. Blin thinks that the meloe proscarabeus made into an ointment with grease, is more useful than any other remedy in the treatment of common cutaneous diseases (*dartres*); and he has proposed to try this salve in tinea.<sup>3</sup> Selle, before this, however, had recommended the same means, which causes the diseased parts to which it is applied, to suppurate as a preliminary to their cure.<sup>4</sup>

Poultices of house-leek (*sempervivum*), and of the greatercelandine (*chelidonium majus*), the juice of the euphorbiaceæ and of other acrid plants, the leaves of the clematis vitalba, the root of the imperatoria, ostruthium, &c., are also occasionally used to stimulate certain chronic inflammations of the skin.

153. The essential oil of turpentine<sup>5</sup> has been tried in some cases of tinea, and of old ulcers, and the animal oil of Dippel<sup>6</sup> has been found efficacious, applied externally, either pure or mixed with common oil, in some cases of phagedenic tinea, and of scrofulous sores. Poncelet had already recommended it, particularly in the latter malady. The remedy ought always to be used mixed with water, or combined with some greasy substance; for when applied pure to inflamed surfaces, it is apt to cause violent headaches. The oil of cajeput, and the petroleum, either alone, or mixed with other substances, have been given internally, in properly regulated doses, and with success, in some obstinate cases of skin disease.

154. Blisters are now and then made use of to divert an eruption of the face or some quarter where it is very troublesome, to another region where it is less apparent or annoying. I have thus succeeded several times, in transferring to the arm or thigh, eczemas that had broken out on the ears, and on the genital organs. In less successful instances, the blisters have only caused new eruptions, without displacing the old ones. It is always proper to establish the drain, before venturing to employ drying or discutient remedies.

155. Blisters<sup>7</sup> are further useful in restoring any eruption, the disappearance of which has shortly preceded attacks of internal disease. It is occasionally indispensable to apply the blister to the very place which the eruption had occupied.

A servant girl was admitted into the Hotel-Dieu, complaining of a sore throat of several months' standing. There was no apparent inflammation of the parts about the fauces, but they appeared drier than usual; on learning that the pain in the throat had followed the disappearance of an eruption (*dartre*) from the fore part of the neck, the physician, M. Bourdier, ordered a blister to be applied to this region; on the morrow, the patient found herself much better, and the dryness of the throat was gone. Having quitted the hospital immediately, she neglected to keep the blister open, and was compelled to return within a fortnight, on account of a renewed attack of her indisposition. Another blister applied to the same spot, was followed by the same happy effects as in the first instance. M. Bourdier now thought of replacing the blister on the neck by one on the arm, but no sooner had the former healed up than the throat again became parched.

Blisters were in succession applied to the shoulders, and to the nape of the neck, but in vain; so that at length it became necessary to apply a third to the immediate seat of the eruption.<sup>8</sup>

No case more conclusive than this as to the point proper to be selected for the application of blisters in skin diseases, can well be imagined.

156. Blisters, so generally prescribed as drains in chronic inflammations of the skin, are almost always hurtful when the disease extends over a considerable district of integument. For children, and occasionally for adults, we prefer the wood of the daphne mezereum, which causes an oozing of ichor, analogous to that of eczema, to the use of the cantharides. I have sometimes imitated the practice of Jaeger<sup>9</sup> in eczema of the hairy scalp, with advantage.—This practice consists in applying blisters to the arms, and keeping them long open.

Electricity is occasionally used as a stimulant in skin complaints in the same manner as blisters.

157. After the sudden disappearance of a spontaneous inflammatory affection of the skin, when any internal disease is set up, the happiest effects are sometimes derived from the use of caustic issues.<sup>10</sup> I have seen subjects sprung of parents who laboured under eruptive diseases of the skin, and who had, without any evident cause, fallen into an indifferent state of health, recover their strength materially after the application of one of these drains.

158. Besides the direct action which it is proper to keep up in the part of the integuments immediately affected in diseases of the skin, it is further very generally necessary to effect some modification in the constitution of those labouring under them. It is to this slow, deep, and searching action, that a multitude of medicines owe their reputation and efficacy. So that the opinion held of old by Oribasius, that the complete cure of skin diseases was not to be accomplished without internal or general treatment, is now very commonly admitted.

159. I have derived the greatest benefit from venesection in numerous chronic inflammations of the skin. Several practitioners restrict the measure of abstracting blood, in affections of the skin, to cases occurring in the strong and lusty, or in subjects of a sanguine or bilious constitution.<sup>11</sup> For myself I declare that I have repeatedly had recourse to blood-letting, with the greatest advantage, even when it seemed to be contra-indicated by the general state of the patient, particularly in elderly persons suffering from sleeplessness caused by prurigos, lichens and eczemas, that had resisted all other treatment. Avicenna long ago recommended the same practice.

In chronic states of inflammation of the skin, the blood is commonly buffy, even in the aged. This condition of the circulating fluid ought to be taken into account, as its appearance might incline us to recur to blood-letting oftener than is really necessary; and we must be very guarded not to change this state of the blood too rapidly by the repeated use of the lancet; the constitution of the patient would inevitably suffer: and further, as I have frequently had occasion to observe, the blood, becoming more and more serous, might, nevertheless, preserve its disposition to coagulate with the buffy coat, and thus lead to serious mistakes. In general, the bleedings ought not to be repeated but at somewhat distant intervals, once a month for instance, and at the periods of menstruation in females labouring under skin complaints, which have been preceded by amenorrhœa or dysmenorrhœa.

160. When recourse is had to blood-letting, the patient ought to be put upon a strict regimen. He ought to have some wild vegetable decoction for his usual drink, and to make habitual use of baths and gentle aperients. Mercurialis<sup>12</sup> managed herpes and lichen during their whole course, by means of diet, general bleeding, leeches, and baths. Some pathologists, however, regard regimen as the mere preparatory treatment to a regular course of purgatives. Others,

reversing the order of this system, prescribe laxatives and clysters before blood-letting. Some prefer combining the action of purgative medicines and of blood-letting, with the occasional use of the tepid bath, the times and occasions of its employment being regulated solely by the state of the digestive organs and of the skin. This last method I hold applicable in a greater number of cases than any of the former. Lastly, to these various plans some have proposed the addition of certain external remedies known by the name of *styptics* and *repellants*, prepared of nut-galls, alum, acetate of lead, &c.; and we are occasionally obliged to have recourse to such measures. Hallé<sup>1</sup> has proposed a method analogous in all respects, with the exception of the bleedings, and which consists essentially in the combined action of purgatives and the warm bath.

The practice of treating chronic inflammations of the skin by the use of purgatives alone has been generally but improperly entitled *Hamilton's method* in France. Besides the fact that there is no mention made of these diseases in this author's book,<sup>2</sup> the practice is very old, and a physician of the name of Joubert<sup>3</sup> wrote particularly upon the subject. It requires to be carefully pursued even when the digestive apparatus appears to be healthy.

Incautiously employed, purgatives sometimes induce a state of morbid irritability in the intestinal canal, followed by reaction of the skin;<sup>4</sup> or they excite chronic inflammations of the stomach and bowels which are difficult to treat, and apt to bring on incurable alterations in the tissues of these parts. It was the fear of these consequences, or *metastases*, as they were termed, that led Van Helmont to reject the use of cathartics entirely in the treatment of diseases of the skin. The same apprehension has of late very much circumscribed their exhibition in France, [in England, however, there is no such reserve; and] I must allow it to be an unquestionable fact that the artificial gastro-intestinal inflammations excited by purgative medicines subside from the moment the action of these remedies is suspended, if the irritation be not kept up and rendered permanent by some individual peculiarity or *idiosyncrasy*.

161. Mild *aperients* or *laxatives* are frequently employed in the treatment of diseases of the skin. Weak infusions of rhubarb sweetened with manna for children, the different saline purgatives, the sulphates of soda, of potash and of magnesia, the tartrate of potash and soda, the sulphate of potash with sulphur, in the dose of one or two drachms in a large quantity of water, or some mild mucilaginous fluid, as also any of the common saline mineral waters, have all essentially the same effects, and fulfil the same general indication.

Sulphur and calomel are also employed as aperient medicines, and, like other purgatives, when prescribed along with a suitable regimen and the use of the tepid bath, are often of service.

162. The ancients regarded active purgatives as very effectual medicines in diseases of the skin: Galen, in the case of a woman labouring under an affection of this description, which was stated to have resisted remedies of every kind, when he learned that purgatives had not been tried, prescribed the strongest *cholagogues*, and in a few days the patient recovered.<sup>5</sup> The rashness of empiricism sometimes gains a triumph over the reserve of the better informed physician: the *powder of Nillaud*<sup>6</sup> has accomplished cures without number. Such results ought to inspire us with greater confidence in this method of treatment, from which I have myself derived the greatest advantages. Whilst prescribing active purgative medicines, we must beware of harassing the constitution of the patient too much, and above all of inducing disorders more serious than the one we are combating.<sup>7</sup>

Oribazius<sup>8</sup> and Aretæus<sup>9</sup> have recommended the *hellebore* in Greek

elephantiasis, and several other diseases of the skin. Galen<sup>10</sup> is said to have cured the leprosy by a copious bleeding, the warm bath and hellebore. Paulus Ægineta<sup>11</sup> employed the same medicine externally. Celsus advises the *black hellebore*, and, in modern times, Schmiedell used the extract of hellebore successfully in two cases of Greek leprosy; Fabricius Hildanus, by the same means, cured a young girl labouring under a very severe affection of the skin; Willan prescribed the tincture of hellebore in the treatment of squamous inflammations; Smith has seen good effects from the ointment of hellebore externally, and the tincture internally; according to Swediaur, fomentations with the decoction and tincture of hellebore, are useful in psoriasis, prurigo and tinea; Bigelow, in inveterate cases of skin disease, recommends a trial to be made of the ointment of the *helleborus viridis*. I am sorry to add that these results, so favourable in appearance, are really of little value. In the first place, there is great obscurity as to the species of hellebore made use of by the ancients,<sup>12</sup> and a serious error was committed when substances so dissimilar as the *veratrum album* and *helleborus niger* were included under the same common denomination. In the hospital of La Charité, I have prescribed the powder of the *helleborus niger* in doses of from 60 to 80 grains, and the tincture of the same plant in quantities of three drachms, without producing the slightest disorder in the digestive functions, or any trace ensuing of modification in the appearances and symptoms of many different affections of the skin. The *veratrum album* must be made the subject of farther experiments.

163. The *gratiola officinalis*<sup>13</sup> has often been used as a purgative in the dose of half a drachm or a drachm in infusion, or of 20 or 30 grains in powder, in the treatment of skin diseases. This plant has even been said to be efficacious in venereal ulcers of the nose and throat; and M. Delavigne has seen it used with success in scabies and several other cutaneous affections. Stoll and De Haen were in the habit of combining *gratiola* with the sublimate in venereal affections generally.

164. The *alkalies*,<sup>14</sup> particularly the liquor potassæ, in doses of 20 or 30 drops, and lime-water,<sup>15</sup> were prescribed by Willan in several, especially squamous, forms of cutaneous disease.

The *subcarbonate of soda* and the *subcarbonate of potash*, in doses varying from a few grains to half a drachm or a drachm in a pint of vegetable infusion, or combined with sulphur, have been tried in several cutaneous affections. *Ammonia*<sup>16</sup> and its subcarbonate have been employed more especially in diseases presumed to be of a syphilitic nature. The subcarbonate is prescribed in doses of 10 or 15 grains, twice a day.

165. The *acids* are more generally and unquestionably useful than the alkalies. Each of them has properties peculiar to itself; in proof of which I can quote the specific action exerted by the sulphuric acid<sup>17</sup> on ulcerated eczema and lichen agrius, and that by the nitric acid on impetigo and pityriasis. The diluted sulphuric acid of our pharmacopœias may be prescribed in doses of from 10 to 20 or 30 drops, two or three times a day, in any convenient vehicle, such as barley-water properly sweetened. Much larger doses than these may, however, be prescribed without impropriety. I have myself given as much as a drachm, and Mursinna has gone the length of even half an ounce daily. The patients ought to swallow these large doses, properly diluted, by little at a time, and even to drink some pure water afterwards, until the stomach becomes accustomed to the medicine.

The utility of the *hydrochloric (muriatic) acid*, diluted with water and administered in grit gruel, decoction of elm-bark, or of dulcamara, has been acknowledged by good and credible practitioners. This acid is usually prescribed in the dose of a drachm or a drachm and a half to the pint of fluid, with an ounce of sugar.

*Nitric acid*,<sup>1</sup> more energetic than sulphuric acid, has been chiefly employed in syphilitic cases. Alyon prescribed the pure acid to the extent of a drachm in two pounds of water, half a glassful to be taken at a time, every two hours, and sucked through a tube to protect the teeth. The strength of this acid varying in the shops from 20° to 42° of the acidometer of Baumé, it is always necessary to indicate the degree of concentration in the prescription. The various sherbets prepared with *acetic acid*, or with the *citric* or *tartaric* acids, are agreeable diluents, rather than very active therapeutic agents.

166. The *preparations of antimony*,<sup>2</sup> first tried in the cutaneous diseases of animals, and afterwards applied by Basil Valentine to the treatment of the same affections among men, have been the subjects of numberless experiments. They are most generally combined with other medicines of a more or less active nature; and I shall take care to mention the most reputed of these compounds when I treat of the diseases in which they have been more especially recommended.

167. The *sulphuret of antimony*, made use of in chronic diseases of the skin by Baldinger and Vögler, and in scabies by Hermann and Tissot, forms the basis of a multitude of quack remedies against skin complaints. Cullen prescribed this substance in the dose of from half a drachm to a drachm, during several successive weeks, without perceiving any effects from its use. In one or two cases only, in which it was given in a very *large dose*, did it excite nausea and vomiting. I have myself ordered it in doses of one, two, and three drachms during the course of twenty-four hours, without any benefit, but also without causing derangement of the digestive organs. It is, therefore, subject of astonishment to observe the care that is taken to adjust and reproduce formulæ in which the sulphuret of antimony is administered in the dose of four, six, or eight grains. As to the remote effects which the sulphuret of antimony exerts on chronic diseases of the skin, they have appeared to me much less conspicuous than such as followed from the *rest* enjoined and the *regular lives* led by the patients in our hospitals; circumstances that mingle with and complicate all our experiments, and that are too often overlooked or neglected by therapeutic inquirers.

The same remarks are applicable to several other preparations, such as the *antimonial ethiops* of Huxham,—a mixture of antimony, mercury, and flowers of sulphur, which has been especially recommended in the treatment of scrofulous complaints. So are they likewise to the ointment of sulphuret of antimony, the effects of which used to be boasted of in several skin diseases, but which never seemed to me to have any other action than that of impure lard. The sulphuret of antimony, as I have said, is often combined with other remedies of greater or less efficiency. Hufeland prescribed it along with sulphureous baths and decoction of dulcamara in doses of a scruple three times a day gradually increased to half an ounce; and this was done successfully, for at the end of six weeks the patient found herself free from the skin disease under which she had previously laboured.

The *decoction of a certain quantity of the sulphuret of antimony* is a much more active medicine than a like amount of the substance in powder. M. Guibourt boiled an ounce of the sulphuret of antimony in sixteen ounces of water till half the fluid was consumed. The filtered liquor, having the hydrosulphate of potash and hydrochloric acid added to it, let fall one grain and 8-10ths. of dry sulphuret of arsenic, which correspond with a grain and 44-100ths. of arsenious acid. This transformation of an insoluble sulphuret of arsenic, which exists mixed with the sulphuret of antimony, into a soluble and singularly active medicine explains how the decoction of the sulphuret of antimony becomes more energetic than the sulphuret itself. I have seen patients take, during several days, half an ounce of the sulphuret

of antimony without feeling any effects from the medicine, but they were rather severely purged by a decoction of only two drachms of the same substance. And it may well be imagined that three-fourths of a grain of arsenious acid could not be taken with impunity at a dose, and this is the quantity of this active poison which the amount of impure sulphuret of antimony specified yields to boiling water.

168. The beneficial effects of those magistral formulæ entitled *tisan of Feltz* and *decoction of Arnoult*, sometimes employed in the French hospitals in diseases of the skin, particularly in those of a syphilitic nature, appear to me owing to the formation of a certain quantity of arsenious acid. These tisans, however, are never identical, for the purity or impurity of the sulphuret of antimony employed, as well as the mode of preparation, makes it impossible they should ever twice contain the same kind or amount of ingredients. Other accidental circumstances may also seem at times to give the sulphuret of antimony properties which it does not possess in fact; the ingestion for example of a mineral acid after a dose of the sulphuret will almost always excite vomiting.

The *sulphuret of antimony* and *mercury* (antimonial ethiops) possess almost the same properties as the crude antimony.

The protoxide of antimony in the dose of the tenth of a grain triturated with sugar and James's powder, has been recommended in diseases attributed to the recession of inflammations of the skin.

169. The *antimonial wine of Huxham* used to be in great vogue in England in cutaneous affections.<sup>3</sup> M. Fages<sup>4</sup> informs us that he treated some of these diseases successfully by the tartar emetic in doses gradually increased. A patient of M. Fages, affected with skin complaints, took, during the first day he was under treatment, half a grain of the tartrate of antimony and ten grains of dulcamara; the dose was gradually increased, and at the end of a hundred and seventy-two days, the patient was taking every day, at two different times, thirty-two drachms of the extract of bittersweet and thirty-two grains of the emetic tartar. Another patient similarly affected took towards the fortieth day twelve drachms of the extract of dulcamara and ten grains of the tartrate of antimony. A third patient by degrees obtained the point when he was consuming eighty-five grains of the extract of rhus radicans and sixteen grains of tartrate of antimony every day.

Several patients whom I have put on this plan, beginning with a grain of the tartrate, were either attacked with diarrhœa or vomiting; others had a number of liquid stools daily; a few only were found who could bear the medicine; but I never got the length of the immense doses of M. Fages. These cases, at all events, prove that habit is an unequivocal cause of the endurance of remedies. In the same manner, and in the same kind of cases as those in which M. Fages prescribed his medicines, some practitioners have tried the effects of an electuary composed of five grains of the extract of poisonous sumac and a grain of tartar emetic.

170. *Embrocations* and *lotions* of the tartrate of antimony have also been employed to bring several chronic inflammatory affections of the skin into a more active state, and to accelerate their termination. Sir W. Blizard applied a solution of the antimonium tartaricatum in tinea,<sup>5</sup> and Dr. Temina<sup>6</sup> prescribed with good effects the same medicine in small doses to the wet-nurses of infants at the breast who were affected with a similar disease. M. Recamier<sup>7</sup> treated successfully a case of gutta rosea with an ointment of the tartrate of antimony.

171. The *chloride of antimony* is used as a caustic in anthracion or malignant pustule; and *Kermes mineral* (the hydrosulphate of antimony) enters into the composition of several salves contrived for diseases of the skin.

172. When chronic inflammations of the skin are set up in weak or scrofulous constitutions, or otherwise, when such diseases are preceded by dysmenorrhœa, amenorrhœa or chlorosis, the principal indication is to modify the constitution, and then the *preparations of iron* are the medicines of most avail: I shall quote many cases in

support of this opinion. Bateman has recommended small quantities of chalybeate wine as well as other preparations of iron to children attacked with impetigo and strophulus. Chalybeate medicines have often appeared to me to be useful in cases of purpura hemorrhagica.

Various *chalybeate mineral waters*<sup>1</sup> have been lauded in the same circumstances. Carmichael<sup>2</sup> has praised the *carbonate of iron* even in cancerous affections; I have tried it several times in cancer of the skin, always unsuccessfully as the disease itself was concerned, but occasionally with advantage to the general constitution of the patient.

173. *Graphite* or *plumbago*,<sup>3</sup> looked upon some years ago as a carburet of iron, now regarded as a kind of carbon or coal containing accidentally some admixture of iron, has been used in the treatment of chronic affections of the skin, from a remark made at Venice, that the workmen employed in the manufactory of pencils were speedily cured of any cutaneous diseases they might have been labouring under when they begun this business. M. Marc informs us that he has used this substance in obstinate herpetic affections. Hufeland also details the case of a lady forty-one years of age labouring under rosacea which resisted every other means, but yielded to the internal and external use of plumbago. In his report from 1817 to 1818 he speaks of the good effects of this remedy. It is administered internally in doses varying from twelve grains to a drachm daily in any form,—powder, electuary or pill; occasionally it is combined with sulphur, and with some mercurial, as the sublimate. The stomach bears the medicine readily, and it is said greatly to increase the secretion of urine after its use has been continued some days; two or three ounces are said to be enough to cure the most obstinate cases. Externally it is best applied mixed with some unctuous body. Contradictory accounts of the value of the plumbago as a medicine have been published in the Medical Journal of Salzburg.<sup>4</sup> My own mind is not yet made up on the matter; I have not had experience enough to enable me to judge.

174. The *preparations of mercury* are universally employed in affections of the skin, both internally and externally.

Geber, Meuse and Rhases are held the first who prescribed *mercurial ointments* in cutaneous affections and ulcers, against pediculi, &c. Employed by Theodorice and Guy de Chauliac in scabies, herpetic eruptions, different species of tinea, plica, frambæsia, and elephantiasis, and subsequently applied by Jacobus Berengarius Carpus and Fallopius to the treatment of venereal affections, various *preparations of mercury* were afterwards administered internally by Vigo, and have not since ceased to be extensively employed in the practice of medicine.

175. *Mercury* in the metallic state, intimately combined with grease, soap, or some vegetable conserve, in the dose of four, six, or eight grains, is a powerful remedy, the action of which, in syphilitic cases, and in some other affections of the skin, is most remarkable and most beneficial. Mercury administered in this form is a much better medicine in general than when rubbed into the system in the shape of an ointment. United with several other substances, mercury has been forced into an immense variety of forms, each possessed of a different degree of activity. It is now found united with sulphur, and now with sulphur and antimony,—the latter, a form that has been recommended by Hufeland, in chronic eruptions of the skin during childhood. Lastly, the black powder called *Ethiop's mineral*, which is produced by combining a quantity of mercury with twice its weight of sulphur, has been tried with some success in several forms of cutaneous disease.

176. Since the experiments of Lalouette were published,<sup>5</sup> cinnabar fumigations have been had recourse to with evident advantage in inveterate syphilitic and other obstinate affections of the integuments, by directing the vapour through a funnel to the affected parts, or ap-

plying it by means of a close box to the surface of the body generally. The quantity of cinnabar used at each fumigation is from half to a whole drachm, and the process is repeated every two or three days. Carelessly administered, cinnabar fumigations are capable of causing accidents of a serious nature.

Mixed with camphor and some unctuous substance, cinnabar forms an ointment that has been recommended in several herpetic eruptions, and against pediculi. It has been prescribed externally by way of friction,<sup>6</sup> and internally in small doses in the treatment of impetigo.

177. The *proto-chloride* and *deuto-chloride* of *mercury* (calomel and corrosive sublimate) enter into the composition of almost all the antihpetic ointments which we find preserved in pharmacopœias and formularies. In the cases communicated to Riverius, we find two of syphilis cured by the use of calomel. Willan and Bateman made extensive use of these preparations in the treatment of cutaneous diseases, and certainly many cases have been successfully combated by their means.<sup>7</sup> I believe myself to have been one of the first who observed that the white precipitate (calomel obtained by precipitation) mixed with lard in the proportion of a drachm to an ounce of grease, applied in frictions to the affected parts in the quantity of one, two, or three drachms daily, exerts a specific power over two forms of squamous inflammation, namely, lepra and psoriasis. I never saw these frictions followed by salivation, which is so frequent a consequence of the internal exhibition, even in very small doses, of calomel prepared in the ordinary way. In this respect, therefore, there is an actual difference between an ointment of precipitated calomel and the common blue or mercurial ointment, the action of which on the salivary glands is constantly the same. I have seen patients labouring under old and inveterate psoriasis use half a pound of precipitated calomel by way of friction, without their mouths becoming in the slightest degree affected, and obtain a perfect cure. Calomel, taken internally, in the dose of five, six, eight, ten, twelve, sixteen, or twenty grains, is commonly followed by several dejections; but besides this action, it exercises another and not less remarkable influence on the constitution. As an alterative, in greatly diminished doses it often excites salivation, sometimes after a very small quantity only of the medicine has been taken. I shall give several cases which prove that calomel applied to the pituitary membrane of the nose, has the power of curing syphilis. In combination with the sulphuret of antimony (Plummer's pill), with the golden sulphuret, or sub-hydrosulphate of the same metal, calomel enters into the composition of a multitude of formulæ, that have possessed and still retain a certain reputation. In fine, calomel internally, and corrosive sublimate externally have been recommended together in many forms of disease of the skin.

178. The *deuto-chloride of mercury*<sup>8</sup> is the basis of a great many simple and compound medicines. Brisbane showed how eminently useful this active substance might become in the treatment of diseases of the skin, when other mercurial preparations had failed to do good. Lorry and many other practitioners have confirmed these fortunate results by their success. I am in the habit of using the sublimate with advantage in the treatment of chronic and obstinate eczemas, in smaller doses, too, than are usual in syphilitic cases. During its use, patients ought particularly to avoid exposure to cold and moisture. I have sometimes combined the action of purgatives with that of the sublimate.

*Sublimate baths*, (from two drachms to one ounce in two hundred pounds of water,) conceived by Baumé, have been particularly applied to the treatment of syphilitic affections; and this mode of administering mercury has been extolled by M. Caffé and M. Wedekind, who have proposed a particular formula for the purpose (half an ounce

<sup>4</sup> Salz. med. chir. Zeit., 1809, 1, p. 337.

<sup>5</sup> Ancien Journ. de Med., tom. xiv., p. 19.

of sublimate and the same quantity of muriate of ammonia to each bath). I have many times prescribed these baths, and have never seen salivation follow their use; but their good effects have also often appeared to me to be very questionable. I have never ventured to order them in a case of scirpiginous ulcerated syphilis, fearing that the sublimate might be absorbed in too large a quantity. The length of time during which the baths are taken, the state of the skin, and especially the degree of aptitude for absorption possessed by the integuments, necessarily influence the advantages and inconveniences of mercurial baths.

179. The sublimate has been employed as a *lotion* in scabies; Gowland's lotion has still some reputation in England in rosacea.—At the Hospital St. Louis, a solution of a drachm of sublimate in a pound of water coloured with *alkanet* root is used as a common wash to cutaneous affections, especially when they are suspected to be connected with a venereal taint. Serious consequences are said to have followed the application of compresses imbibed with an empirical wash, analogous to the preceding in its composition. Concentrated solutions of corrosive sublimate are sometimes used to destroy condylomata. I have already mentioned mercurial pediluvia in the treatment of syphilitic affections.

180. M. Werneck has tried the *bromate of mercury*<sup>1</sup> in cases of obstinate skin complaint. I have not myself any experience of the effects of this compound.

181. The *iodates* or *iodurets* [*iodides*] of *mercury* are energetic preparations, the effects of which have appeared to me eminently beneficial under many circumstances, particularly in chronic tubercular and papular inflammations of the skin. They are especially available in the treatment of syphilitic affections complicated with scrofula. The *deuto-ioduret* is even a more active preparation than the corrosive sublimate itself. Externally applied, it has sometimes been found sufficient to leave the deuto-ioduret in contact with the skin for a while, to induce a most intense erysipelatous inflammation.—When it is given internally, it is proper to begin with the sixteenth part of a grain, and to raise the dose gradually to an eighth; very rarely will it be prudent to exceed a quarter of a grain.

The *proto-ioduret of mercury* which is less energetic in its action than the deuto-ioduret, is used internally, under the same circumstances, in doses of half a grain, which may be gradually increased to one or two grains. Externally, I sometimes make use of an ointment of the proto-ioduret of mercury, to aid the resolution of the tubercles of lupus, of rosacea, of syccosis, &c.

182. The *cyanuret* [*bicyanide*] of *mercury*,<sup>2</sup> extolled by Chaussier and by Horn, has recently been recommended by Dr. Thomson, mixed with lard, in rosacea, eczema, and several other chronic inflammations of the skin. This substance has such powerful effects on the animal economy, that the first doses ought not to exceed the sixteenth part of a grain in amount, when it is prescribed internally.

183. The *red oxide of mercury* enters into the composition of a multitude of ointments, which are often employed with advantage in chronic inflammatory affections of the skin.

184. The *proto-nitrate of mercury*, mixed with lard, has also been employed, by way of inunction, in the treatment of many diseases of the skin. Dissolved in water, it has been applied successfully in porrigo, and the diseases attended with pediculi.

185. The phagedenic inflammation of lupus exedens, and of scirpiginous syphilitic affections, is often stopped by one or more applications of the nitrate of mercury with the acid in excess.<sup>3</sup> A drachm of the proto-nitrate of mercury is dissolved in an ounce of nitric acid; a pencil dipped in this solution is the best means of applying it to the diseased surface. In case a greater effect is desired, a compress of lint, steeped in the solution, may be maintained in contact with the sore for any length of time. Many cases of lepra and inveterate psoriasis have been cured by this treatment.

186. The *sub-deuto-sulphate of mercury* (turpeth mineral) which has been mentioned as a preservative against small-pox, has been

successfully employed internally in the treatment of many obstinate skin complaints in doses of one-fourth of a grain repeated two or three times a day. The dose may be gradually increased to two or three grains. By mixing this preparation with lard in the proportion of one to eight, an ointment is formed that may be often advantageously employed in stimulating certain chronic affections of the skin, particularly psoriasis of an old and inveterate character.

187. The *preparations of gold*<sup>4</sup> have been found available in the treatment not only of syphilis but of favus, and of some other chronic inflammations of the hairy scalp. They appear particularly well adapted for inducing modifications in the constitution of scrofulous subjects attacked with skin disease. M. Chrestien has detailed the mode of exhibiting these preparations, which I shall notice by and by when I speak of syphilis, eczema and pityriasis.

188. The *preparations of arsenic*<sup>5</sup> appear to have been used for the first time in Europe, in the treatment of diseases of the skin, by Adair, and Girdlestone, of Yarmouth. The latter tried the arsenical solution of Fowler, in a case of lepra in which he had existed during fourteen years, and the patient recovered under the influence of small but repeated doses of the medicine. He informs us that he subsequently obtained hundreds of cures of lepra, prurigo, psoriasis and tinea. The second case of lepra in which he tried arsenic, exhibited phenomena that particularly attracted his attention. After three doses, each of eight drops of the solution, the whole body of the patient became as red as a lobster, and the face appeared as if it were attacked by an incipient erysipelatous inflammation. The use of the medicine was immediately suspended till the redness of the skin subsided, and it was then only resumed in doses of half the former amount, under which the leprous affection gradually disappeared. In a third case, the cure of the leprosy was preceded by an eruption of large bullæ on the hips. The curative effects of the arsenical solution indeed were often observed to be preceded by an increase of the eruption, by a crop of blebs, or by chaps in the skin of the feet and toes, and of the hands and fingers. A patient who had laboured for two years under *lepra nigricans* which appeared in large patches on the cheeks, and had resisted various plans of treatment, was put upon four drops of the arsenical solution twice a day: the first dose produced a great degree of redness of the skin, tension of the belly, and a slight fainting fit. The patient found relief from a grain of calomel, and the lepra was subsequently got rid of by two drops of the solution taken twice a day during six weeks. Having suffered a slight relapse, the patient resumed the medicine in doses of four drops, which caused the same disagreeable effects as at first; but he ultimately recovered without any inconvenience under the continued use of the solution in doses of two drops at a time. The largest dose of Fowler's arsenical solution Girdlestone ever thought advisable to prescribe, was twelve drops three times a day. Six drops, however, he afterwards found to be a sufficient dose for all good purposes. Although he sometimes succeeded within a few days in lessening the severity of the symptoms of the skin disease, he found by experience that he could not consider the cure as accomplished, under any dose to which the medicine could be carried with propriety, unless its use were continued during six or seven weeks at least. One patient took the arsenical solution in the dose of twenty drops three times a day for more than three months before the lepra under which he suffered disappeared. This patient had many nervous symptoms, fainting fits, attacks of diarrhœa, &c.; accidents which, in spite of the greatest care, continued during several weeks. Weakness, pains of the abdomen, nasal hemorrhage and cough, as also hepatic and dropsical symptoms, all accompany or follow the ill-regulated exhibition of this powerful medicine. Too strong doses cause the urine to acquire a jaundiced appearance. When the bowels are constipated, the arsenical solution suffices occasionally to render the motions regular, and when diarrhœa comes on, a quarter of a grain of opium two or three times a day corrects this effect of the medicine. It is always proper to begin the use of arsenical medicines in very small doses, never to be tempted to carry the ordinary solution beyond five or six drops three times a day, and

to persevere in its use so long only as it is unattended by evil consequences. In children the doses must be smaller—one, two, or three drops, once or twice a day.

The arsenical solution is a remedy that has been greatly abused in squamous affections of the skin; Mr. Duffin, however, has employed it in many cases along with a decoction of dulcamara, of mezereon bark, or of sarsaparilla with advantage. He supposes that small doses taken at short intervals are more useful and more certain in their effects than larger doses at longer intervals. It is rarely necessary in this way to prescribe more than ten drops of the arsenical solution three times a day, six are generally found sufficient, and before long—ten or fifteen days at most—the effects of the medicine are apparent not only on the disease, but on the constitution of the patient. The first symptom the medicine produces is a sensible acceleration of the pulse, which, under its continuance, may be found to have risen from twenty to thirty pulsations per minute above its ordinary rate. The pulse further acquires fulness and hardness; the patient soon begins to complain of tingling sensations in different parts of the body, itching and pain of the eyes, &c.; the eyelids, especially the lower, become puffed, and the eye is surrounded by a slight dark and livid circle. These symptoms sometimes precede the acceleration of the pulse. If the remedy be still persisted in, the patient complains of weakness of stomach, pains of the bowels, and sometimes of shooting pains in the chest; the tongue becomes white, the countenance alters, and the expression acquires a sorrowful cast; anxiety about the præcordia, and other distressing symptoms supervene at last and compel the use of the poison to be suspended—these symptoms, indeed, show that it has been continued too long; it should always be abandoned when the acceleration of the pulse and swelling of the eyelids are observed.

The physicians of America have also tried the arsenic in several forms of cutaneous disease. Dr. Rush prescribed the arsenious acid in the shape of pills in various severe affections of this nature. The dose he ordered was the 15th, the 10th, and the 8th of a grain twice a day, mixed with soap, causing the patients at the same time to make use of an infusion of the *eupatorium perfoliatum*. M. Valentin, who makes us acquainted with this fact, has seen several patients follow the plan of treatment indicated above, during more than two months without any good effects on their disease, but also without any apparent alteration of their health. Willan and Bateman also extolled the effects of Fowler's arsenical solution in obstinate cases of lepra, of lichen, of prurigo and of porrigo. They assure us it may be administered with perfect safety if cautiously managed; but they do not appear to have studied its special effects on the constitution with the same care as Fowler and Girdlestone.

In the reflections on the use of arsenic, read before the Lyceum of Philadelphia, in 1812, by Dr. I. Redman Coxe, the author, after having combated the repugnance that is generally felt to the use of this medicine, relates the case of a lady who had laboured under leprosy during fourteen years without deriving any benefit from every kind of the most active treatment, but who recovered under the use of the arsenical solution continued for two years and a half, and taken at last in doses of fifty drops three times a day. There was this peculiarity in the case, that just as the disease was beginning to yield, the patient could not take more than five drops of the solution three times daily without having tumefaction of the face, nausea, loss of appetite, sense of weight in the eyes and head,—symptoms that proclaimed the necessity of suspending the large doses for a season. (a) Dr. Otto, of Philadelphia, published about the same time an account of three cases of obstinate eruption which had resisted the use of sulphur, of antimony, the corrosive sublimate, and mercury in other shapes, pushed till the mouth was affected, but which yielded to the arsenic. Two years afterwards there was not the slightest appearance of the disease, and no trace of ill consequence from the use of the medicine. Dr. Bardsley, of Manchester, has also employed Fowler's solution in cutaneous diseases; but he dissuades from the too long continuance of the remedy, as he fancied he had observed the arsenic to accumu-

late in the system and to produce bad effects, such as flying pains, flatulence, paralytic affections of the limbs, &c. M. Fodéré<sup>2</sup> used Fowler's solution with success in some obstinate cases of skin disease. A gentlewoman, thirty years of age, exposed, from the particular circumstances in which she was placed, to many privations and hardships, was, among other complaints, affected with an obstinate sealy eruption (*dartre ecailleuse*) of the hands, which obliged her to work in gloves. This patient had in vain tried remedies of all kinds. The first effect of the arsenic, which was at length prescribed, was to regulate the menstrual function that had long been disturbed, to render the breathing free, and the complexion clearer; but as yet the disease was untouched, although a considerable quantity of the medicine had already been taken. M. Fodéré, however, desired its use to be persisted in, and at the end of a month he was desired to visit his patient whom he now found labouring under bronchial affection, with bloody expectoration; at the same time the disease of the skin had disappeared, and the hands were perfectly whole. The present more pressing malady was treated by soothing remedies, and the arsenic was discontinued for a month. After this period the skin complaint reappeared, but the patient having again resumed the arsenic, the hands were anew restored to their natural condition, with the exception of a slight degree of remaining roughness of the skin.

189. M. Jourdan has collected, under the head *Arsenic*, in his *pharmacopée universelle*, almost every preparation of this metal that has ever been employed in medicine; but I have contented myself by giving those only among my *formule*<sup>3</sup> which have been more particularly recommended in diseases of the skin. I have been particularly attentive to indicate the occasions proper for the employment of these energetic remedies, to specify their respective doses, and to show their physiological and therapeutic agency, their advantages, and their occasional ill effects. Certain chronic and obstinate forms of eczema of the scrotum, margin of the anus and labia, are, of all the vesicular inflammations, those in which arsenical medicines are most frequently and most successfully employed. This class of remedies ought never to be had recourse to in exanthematous inflammations; they are also rarely useful, and sometimes dangerous, in chronic bullous inflammations. Among the papular inflammations, the circumscribed, the confluent, and chronic lichens occasionally require their use. They have been often abused in prurigo, in pityriasis, psoriasis, and lepra, which they, nevertheless, sometimes attack with success. When these diseases are inveterate, the prolonged and continued action of arsenical medicines is apt to alter the mucous membrane of the digestive organs, and to implicate the constitution without modifying the diseased conditions of the skin for which they were especially prescribed.

190. I shall have occasion to analyze the observations of Mr. Robinson, and those of Mr. (I.) Wilson, on the use of arsenical preparations in the treatment of the Greek elephantiasis. Experience has taught me, that not only are the deep alterations of the skin which characterize this disease externally not removed by these medicines, but that they sometimes even cause disorders and grave complications when their use is persevered in for several months continuously, or alternated with other active remedies. In one case of Greek elephantiasis, M. Delpech administered Fowler's solution without any benefit during two months; the only effects it had were to cause a diminution of appetite, slight purging and some emaciation.

191. Independently of the changes which arsenical preparations may produce in the digestive organs, and of the tremors and paralytic affections of the limbs, observed by different authors, the following case, as well as two others I possess of the same kind, tends to show that, administered unseasonably, they may induce true paralysis of the genital organs. I had under my charge, in La Charité, a letterpress compositor, twenty-three years of age, in La Charité, a letterpress compositor, twenty-three years of age, labouring under lepra and chronic enteritis. Although of weakly constitution, this man had hitherto enjoyed perfectly good health. He had been attacked about five years before by lepra vulgaris on the knees and elbows, but by degrees the disease extended to all the other parts of the body. During the first two years, the disease was treated by simple baths, by baths

(a) See, also, a paper on the same subject by Dr. D. Theodore Coxe, in *North. Am. Med. & Surg. Journ.*, vol. viii.

<sup>1</sup> Medical Reports, &c. London, 1807.

<sup>2</sup> Journ. compl. des sc. médic., t. 1, p. 117.

<sup>3</sup> These will be found at the end of the volume.

of sulphur and other preparations of this mineral. During the third year the patient tried various remedies, and was at last put upon the use of Fowler's solution, which he took in doses gradually increased from five to twenty drops, for three months. Shortly after having undergone this treatment, he began to complain of pains in the stomach, his digestion was disturbed, he lost his strength, he was taken with a profuse diarrhœa, and his genital organs were completely paralyzed. This state of affairs had already lasted eighteen months, and the patient told me that the diarrhœa was excited afresh by the slightest freedom in diet.

Preparations of arsenic imprudently applied to the exterior may also occasion serious consequences. A young woman having made use of an arsenical ointment to her hair for the purpose of destroying the pediculi with which she was infested, was attacked five or six days afterwards with a tumefaction of the whole head; the ears were double their natural size, and covered with incrustations; the sub-maxillary and cervical glands, even the parotids, swelled rapidly; the eyes were sparkling and prominent, the face puffed and almost erysipelatous; the pulse was hard, the tongue dry, the skin hot and parched, and the other symptoms of violent fever were present. The patient, in addition, suffered from vertigo, a sense of approaching syncope, cardialgia, vomiting at intervals, scalding in making water, obstinate constipation of the bowels and tremors of the limbs, with inability to rise into the erect posture. At last delirium was added to the list of other ills. A copious bleeding was immediately practised, which was ordered to be repeated in the night if the symptoms seemed to require it. Diluents of chicken broth, emollient clysters, pediluvæ, &c., were prescribed, and the head was rubbed with an ointment containing a fourth of its weight of chalk in fine powder. Next day there was some improvement, but also considerable disposition to somnolence. A few leeches were applied to the thighs. The succeeding night was restless; the tumefaction of the head seemed to have increased, and towards morning the whole body, and particularly the feet and hands, were observed to be covered with a pretty copious eruption of small pimples with white heads, like millet seeds. The patient was very weak, and could not sit up without uneasy feelings about the præcordia. Laxative medicines were now exhibited, and within forty-eight hours the eruption dried up, and fell off afterwards in scales; the bowels became open, and all the symptoms abated. During her convalescence the patient lost her hair.<sup>1</sup>

192. To recapitulate:—arsenical preparations are most energetic medicines, of incontestable use in various severe forms of cutaneous disease. They act especially on the digestive organs, on the integuments, and on the nervous system, as the observations published on their operation and curative effects demonstrate. These preparations ought to be prescribed internally at first in very small doses—the 16th of a grain of the white oxide of arsenic, for instance, once or twice a day, for an adult,—a dose that may be gradually increased to an 8th, a 6th, or a 4th of a grain, but very rarely further, although a whole grain has been given; in this quantity, however, the remedy may act like a poison. Before venturing on the use of arsenic, it is proper to be certain that the digestive organs are perfectly healthy and not disposed to become permanently deranged under the influence of a stimulating plan of treatment, especially if this is proposed to be continued for some time. Prudence occasionally requires us to administer these medicines ourselves, and not to entrust our patients with more than very small quantities of them at a time. Their effects on the digestive organs and nervous system ought to be sedulously watched every day; should the doses we have adopted or attended to, cause any unpleasant symptoms, they must be lessened or suspended for an interval, and when they bring on pains in the epigastrium, constriction of the throat, anxiety about the præcordia, spasms, sickness, diarrhœa, &c., their use must be given up entirely: this is better than attempting to subdue these symptoms by narcotics. In treating chronic diseases of the skin by arsenical medicines, the fact must always be borne in mind, that the sensible effects of these remedies, slow and silent at the beginning, may suddenly acquire greater intensity and prove the cause of lesions more or less severe in their nature.

If it be allowable cautiously to try every known means in the treatment of rebellious diseases, it would be culpable temerity to persist for too long a time in the use of remedies possessed of such energetic actions on the economy, that they are apt themselves to become the cause of serious disorders.

193. The obstinate characters which the chronic diseases of the skin occasionally present, have led to some bold experiments on the internal use of *cantharides*. Employed in the time of Pliny, and not always with the best effects,<sup>2</sup> in lepra and the lichens, recommended by Avicenna and Mead,<sup>3</sup> in the treatment of Greek elephantiasis, and more recently<sup>4</sup> in various other cutaneous diseases, cantharides is a medicine which, in the shape of tincture, is now very frequently employed in lepra, psoriasis, and several other chronic affections of the skin. I shall be particular through the course of this work, especially when treating of lepra and psoriasis, in insisting on the precautions which are requisite not to turn, at the very outset, an active remedial agent into a deadly poison. I may, however, just observe here, that if it be well proved that the tincture of cantharides has often caused the disappearance, in a few weeks or months, of certain skin complaints, which had resisted every other form of treatment, it is not less certain that patients have occasionally taken even as many as 150 doses, of 10, 15, 20, and 30 drops of the medicine, and that others have used it uninterruptedly during several months, without deriving from it any benefit whatever. It is impossible to overlook the circumstance, also, that whatever the skill and care of the practitioner in the exhibition of this medicine, the genital and urinary organs will, in a greater or less degree, always become affected. I have seen some patients worn out by painful erections, and others labouring under unequivocal symptoms of inflammation of the bladder in consequence of its use. Females in general bear this medicine much worse than men.

To complete this review of the many therapeutical experiments to which the diseases of the skin have given occasion, I have still to speak of a great number of vegetable substances whose curative effects in these complaints have been admitted on grounds of different degrees of worth and stability.

194. Various species of *asclepias*<sup>5</sup> (*Asc. Gigantea*, *Asc. Vincetoxicum*, Linn.) have been recommended in the treatment of lepra, of frambœsia, of elephantiasis, and other obstinate cutaneous affections.

195. Knakstedt has published, in the memoirs of the academy of St. Petersburg, a notice in which he shows that the root of the *elecampane* (*Inula Helenium*, Linn.<sup>6</sup>) administered internally, and applied externally, is extremely efficacious in eruptions and other diseases of the skin. In many districts this root, reduced to powder, and incorporated with grease, is a popular remedy in scabies.

196. Sudorific properties, of some avail in cutaneous affections, have been ascribed to monkshood or *aconite* (*Aconit. Napellus*, Linn.<sup>7</sup>). Tommassini has, however, prescribed the extract of aconite in doses varying from 10 to 90 or 100 grains daily without success in a case of syphilitic eruption (*dartre syphilitique*). On the other hand, we have accounts of the aconite, even in small doses, producing serious accidents, lypothymia, vertigo, general tremor, &c. I have tried the drug myself, not only in diseases of the skin, but also under other circumstances; and I find that the medicinal extract of monkshood varies extremely in its action, according as it is procured from the aconite of the hills or from that cultivated in gardens, according likewise to the care with which it has been prepared and preserved. I find further

<sup>1</sup> Recueil périodique de la société de méd. de Paris, t. vi., p. 22.

that it rarely produces similar or salutary therapeutical effects, given in such doses as medicines of the same class are usually prescribed.

Proposals have been made to combine the aconite with the deutocloride of mercury, in the treatment of syphilis.

197. Stoerck has advised the extract of the *anemone pratensis*<sup>1</sup> in several diseases of the skin in doses of one or two grains daily. M. Bonnet has succeeded in curing obstinate eruptions (*dartres*) by the exhalation, twice a day during some months, of one grain and a half of extract of anemone mixed with eight times its weight of sugar. The affected parts were washed with a decoction of hyoscyamus and of hemlock. Chomel speaks of applying the anemone *nemorosa*, Linn., to the head in cases of tinea. Other observations have been published in favour of the anemone *pulsatilla*.

198. A decoction of the root of the bur-dock (*Arctium Lappa*, L.)<sup>2</sup> in the proportion of one or two ounces to the pint of water, has been used with some advantage in inflammation of the skin that had gone into the squamous or furfuraceous state. The use of this decoction requires to be continued for several months, as it only acts with extreme slowness. It seems to have been a frequent practice formerly to apply the leaves of bur-dock bruised to the head in chronic affections of the hairy scalp.

199. *Hemlock* (*Conium maculatum*, Linn.)<sup>3</sup> has been recommended not only in various less formidable shapes of skin disease, but also in the treatment of scrofulous [and even of cancerous] sores; Joannes Vigo, in the 16th century, was the first who employed this plant in herpetic affections, (dans les dartres,) and this is one of the forms of skin disease, in which Stoerck has recently found it most beneficial. Hufeland prescribes it both internally and externally in affections of the hairy scalp: Murray only ventured on its outward use.—Syphilitic affections have been subdued by the officinal hemlock.

200. In a number of diseases the principal indication is often to effect some modification of the general constitution; this indication, indeed, at times absorbs all the others. We have consequently been recommended to treat those complaints to which people of a scrofulous, lax, and lymphatic habit are subject, by the juices of the cochlearia officinalis or scurvy grass, of the cochlearia armorica or horseradish, of the water-ress (*sysimbrium nasturtium*), by watery infusions and beer of the hop (*humulus lupulus*), of the buck-bean (*menyanthes trifoliata*), of the stone crop (*sedum acre*) house-leek, (*sempervivum teetorum*), &c. On the same principle decoctions of Peruvian bark, of the Virginian snake-root, &c., were employed to sweeten the blood, and remedy the cachectic state of constitution observable along with the appearance of impetigo scabida in elderly people, and of rupia and ecthyma luridum, at all ages.

201. J. Bauhinus employed the *colchicum* externally to destroy pediculi of the head and pubes. Dr. Elliotson<sup>4</sup> cured a man sixty years of age of prurigo, in three weeks by the use of half a drachm of vinum colchici three times a day. I have obtained some success myself from the use of the tincture of colchicum, in several cases of lichen complicated with hereditary gout or rheumatism.

202. A great number of cases collected by Carrere, Razou, Bertrand-Lagrèsie, Crichton, and other physicians, leave no doubt as to the value of the *Dulcamara* or bitter-sweet (*Solanum Dulcamara*, L.)<sup>5</sup> in the treatment of eczema, and squamous inflammations of the skin. If Messieurs Desbois and Alibert failed in deriving the same good effects from this medicine, their want of success must be attributed to their having used it in too small doses, or to their having made but short trial of its efficacy; for if the dulcamara produces no good in some cases, it is certain that in others its beneficial influence is speedily

apparent. Neither must it be forgotten that whilst simple psoriasis of the elbows and knees often withstands the freest exhibition of this substance, chronic inflammations of the same kind, extending to large surfaces of the integuments, are frequently seen yielding readily to doses much smaller in amount. In every case the dose of the remedy should be gradually increased. I have used as much as four ounces of the root in decoction in the course of four and twenty hours, and from two scruples to two drachms of the extract in the same interval of time.

Baths of decoction of dulcamara have been recommended in the same kind of affections as those in which the decoction and extract have been given internally, and especially in those syphilitic eruptions which have withstood the influence of mercury. I have never studied the action of these baths.

203. Galen, Oribazius, Ætius, Avicenna, and Mesue, among the ancients, and among the moderns, Gilbert, Pinel, Sprengel, and others, agree in considering the herb *fumitory* (*fumaria offic.* Linn.)<sup>6</sup> as useful in scaly tetter, and even in elephantiasis. The expressed juice usually exhibited, during two or three months in the spring, in doses of from two to six ounces, may be subsequently increased to twelve. Menuret prescribed the extract of fumaria combined with hemlock and calomel. I have myself sometimes employed this plant medicinally, but always in union with other remedies of different degrees of energy, a circumstance that prevents me from giving an opinion upon its peculiar properties.

204. M. Loiseleur de Longchamp prescribed with success the leaves of the *Daphne gnidium*,<sup>7</sup> the use of which had already been recommended by Russel, Wright, and Swediaur, in diseases of the skin. Cullen tells us that he had seen numerous ulcers of the skin persisting after a mercurial course, get well under the use of the decoction of this substance continued during two or three weeks. Sinclair has made some experiments on the *Daphne mezereum*, which Rouch exhibited combined with gum benzoin. On the other hand Wedel and Hoffman have lifted their voices against the daphne gnidium, reproaching it with having caused burning heat of the stomach, cardialgia, shooting pains of the bowels, hypercatharsis, &c. I have seen, and have myself prescribed the decoction of the bark of this plant to many patients; and whilst I allow that several experienced such symptoms as those I have just mentioned, I have still to add that in no case were they so violent as to make me regret having given the medicine a trial.

205. *Tar-water*<sup>8</sup> is a very ancient internal remedy in chronic diseases of the skin. In the Pharmacopœias of Edinburgh, Dublin and the United States of America, formulæ for different unguents and liniments as external applications, into which tar enters as an ingredient, may still be found. I commonly mix one part of tar and four of hog's lard to make an ointment, which I often find to prove effectual in papular inflammations, and especially in prurigo. Pitch has been exhibited internally in a dose of from half a drachm to half an ounce every day, in chronic ecthyma, and several inflammations of a squamous nature.

206. Those vegetables characterized as *sudorifics*,<sup>9</sup> such as sassafras, sarsaparilla, guaiacum, &c., are powerful remedies in syphilitic and several other cutaneous affections. In our practice these substances are commonly exhibited in too small doses; I have pushed them advantageously to the length of 6, 8 or 10 ounces daily in decoction during one or two months.

207. The infusion of the Acorn,<sup>10</sup> and of the Galium aparine; the juice of the *Ceanothe crocata*, the extract of the bark and husk of the *Juglans regia*,<sup>11</sup> the decoction of the bark of the *Ulmus campestris*, and especially of the *Ulmus pyramidalis*,<sup>12</sup> of the *Rumex patientia*, *Rumex acutus*,<sup>13</sup> and stems of the *Viola tricolor*,<sup>14</sup> infusions of the

*Ledum palustre*,<sup>1</sup> and of the *Rhododendron chrysanthum*; the extract of the leaves of the *Rhus toxicodendron radicans*<sup>2</sup> in the dose of fifteen to twenty grains three or four times a day, carried, within the space of six weeks, to the extent of from half to a whole ounce in the four and twenty hours; the decoction of different species of *Scabiosæ*, as of the scab. succisa, scab. arvensis, and their juice in doses of two, three or four ounces, and various other vegetable extracts, infusions and decoctions, have been recommended in skin diseases, of various characters and appearances.—Although I have collected a certain amount of practical information on the action of these substances, I have still many doubts unresolved as to the peculiar effects and degrees of efficacy, in a therapeutical point of view, of many of them: it will be seen, however, that I have made the study of their properties a particular subject of attention, and that I have constantly endeavoured to discover the circumstances which render their exhibition more rational, and their usefulness less a matter of uncertainty than it is.

208. I shall conclude this therapeutical review by a few critical observations.

The numerous and diversified experiments which the obstinacy and frequent relapses of cutaneous diseases have provoked, are unquestionably not without their importance; but it is an abundant mine from which careful study and observation alone teach us to extract the treasure. Moreover, if it be a fact that many remedies, such as purgatives, antimonial preparations, sulphureous and arsenical medicines, &c., are at the present time successfully employed in almost all the chronic diseases of the skin, whatever their form, and whatever the order to which they belong; it is not less evident that more accurate experiments, made under more determinate conditions, that is to say, with reference to well-ascertained species, must be more useful, and more easy of application: such has been, and such necessarily required to be, the end and aim of my own experiments.

From these therapeutical essays, too, there results the sad truth, that obstinate diseases have been opposed by remedies of the most opposite descriptions in their physical and chemical properties; and that, even at the present time, it is often difficult to decide upon the choice of a remedy, or to reason on the propriety of its exhibition.

It is also easy to perceive why physicians who have been struck with the salutary nature of certain inflammatory affections of the skin, and who have observed the evils that sometimes follow their cure or disappearance, or who have felt discouraged with their frequent relapses, have been led to pursue a purely expectant or palliative plan of treatment, or to substitute for these diseases some sort of drain, or issue, or artificial inflammation; a practice which, on the continent, is still frequently followed in the cases of children and elderly persons. Other practitioners have evidently viewed inflammations of the skin as external phenomena, connected with internal conditions more serious and important in their nature, and they have acted on the notion that it was impossible to accomplish their complete cure otherwise than by effecting some great modification of the constitution by regimen and appropriate remedies. To those of a sanguineous temperament and plethoric habit, they have recommended bleeding, the warm bath, milk diet, &c.; to the scrofulous, tonic bitters, preparations of iodine, &c.; to those disposed by descent to herpetic or scaly eruptions, sulphureous, antimonial, arsenical preparations, &c. Other practitioners, without losing sight of the important and even necessary distinction between *constitution* and *disease*, have nevertheless given themselves up to the search after *specific remedies* adapted to each particular kind of skin disease, and to each of its periods; they have insisted on the propriety of the system of expectation, or moderate antiphlogistic plan, in eruptive fevers; on the virtues of mercurial preparations in the syphiliticæ; on those of sulphureous medicines in scabies and chloasma; on the demonstrated usefulness of natural and artificial sulphureous waters in a great number of cutaneous affections; on the advantages of depilation in favus of the hairy scalp; on the good effects of the sherbets of the nitric and sulphuric acids in lichen and prurigo; of the iodurets in scrofulous lupus; of chalybeate medicines in cutaneous inflammations complicated with

amenorrhœa, dysmenorrhœa, &c.; acknowledging, however, that in some obstinate cases recourse must be had alternately to bleeding, purgation, vapour baths, alkaline baths, arsenical preparations, &c., before a permanent cure can be obtained. Others, again, having found by experience the advantages derived from acting on the immediate seat of the disease by means of simple or variously medicated baths and fomentations, lotions, cataplasms, unguents, fumigations, stimulants, cauteries, &c., have insisted on the great value of *external remedies*, which, indeed, are generally efficacious when the alterations of the skin to which they are applied are merely local, or when their action, like that of the preparations of sulphur, of arsenic, of mercury, of iodine, &c., exhibited internally, is extended to the constitution at large, or when they are combined with the internal exhibition of such medicines as exert this powerful influence.

Lastly, it is undeniable that theoretical views have often given particular turns to therapeutical investigations, which have been of service to science. Thus the known uses of purgatives and emetics would not have been discovered at so early a period, without the *bilious* origin attributed by the old writers to diseases of the skin; the inconveniences attending the exhibition of these and other medicines, such as the preparations of antimony, of arsenic, of cantharides, &c., would not have been inquired into so diligently, and exposed with so much zeal, but for the severe attention with which the partisans of the physiological school in these latter days have studied the diseases of the stomach and apparatus of digestion,—without the systematic tendency in this sect to exaggerate the sensibility and the influence of the gastro-intestinal sympathies,<sup>3</sup> previously ill conceived, or entirely overlooked by practitioners, whose minds were too exclusively occupied with the state of the integuments.

To recapitulate:—it is necessary, would we bring the treatment of an affection of the skin to a successful issue, to recall to mind its natural progress; to calculate the probable amount of its beneficial or noxious influence on the constitution, its relations with the general state of health or with preceding diseases, and its affinity to other maladies, whose ulterior appearance is more or less to be apprehended; it is further needful to estimate beforehand the extent of the influence which will be exerted by a change of the diet and general mode of life, not only on the disease, but on the constitution; the effects of age and of climacteric changes must also be taken into account; lastly, from among the therapeutic agents at our disposal, that one must be selected which appears at once best adapted to the individual constitution, and to the nature, severity, extent and date of the disease. As now stated, this problem is more complex than it appears at first sight: the true therapeia of cutaneous diseases must be sought for in the history of their species, and better still in the observation and comparative study of a great mass of particular cases.

## OUTLINES OF THE PATHOLOGY AND REMEDIAL TREATMENT OF DISEASES OF THE SKIN.

BY THE AMERICAN EDITOR.

He who will carefully peruse the "*Introduction*" and "*Preliminary Observations*," to the present work, can hardly fail to acquire an extended view of the general pathology and therapeutics of cutaneous diseases; but as these, by their very fulness, may not, perhaps, be as readily comprehended and distinctly remembered as could be desired, it has seemed to the editor that he might render an acceptable service to the practical investigator into these matters by a condensed summary of the subject, in which it is not, however, his intention to restrict himself entirely to the Treatise of M. Rayer.

Without entering into details of the minute anatomy of the skin, it is enough for us to be aware of the fact, that this portion of the tegumentary system consists of two main layers, viz., the *epidermis* or scarf skin and the *dermis* or true skin. Each of these again is subdivided into other layers; the superficial layer of the epidermis is the cuticle, and the deeper layer, the *rete mucosum* or *rete Malpighii* of older writers;

<sup>1</sup> Linnæus. De ledro palustri. Upsal, 1775.

<sup>2</sup> Dufresnoy. Des propriétés de la plante appelée rhus radicans. Paris, 1788.

<sup>3</sup> I own that I have myself shared and abetted in extending this mistake. Vide Art. Estomac, Dict. de Sc. Med., in 18 vols.

the upper layer of the dermis is named the papillary; the lower one, or sub-stratum, the corium or corion. The epidermis is properly a secretion from the dermis, which it serves to protect. At first fluid, it becomes solid, gradually and in proportion as it is separated, layer after layer. Its inner layer, the *rete mucosum*, is soft and cellular, and in contact with the papillary layer of the dermis, from which latter it receives its form. Breschet and Roussel de Vauzeme, to whose labours we are most indebted for our present knowledge of cutaneous structure, have compared the *rete mucosum*, in its conversion into epidermis, to recently melted wax, one half of which is liquefied by heat, while the other is condensed by the external cold. The cuticle, or external epidermic layer, is laminated in its texture, and as the superficial laminae are continually removed by attrition, new ones are as continually reproduced upon its internal surface. The degree of thickness of the cuticle is dependent on, and bears an accurate proportion to the degree of development of the papillae of the dermis. The epidermis is accurately modeled on the papillary layer of the dermis, and each papilla has its appropriate sheath in the newly-formed epidermis or *rete mucosum*. The colour of the skin, varying in different races, and even people of the same race, is owing to the presence of pigment in the cells of the epidermis. The pigment cells are most abundant in the furrows of the dermis, and in the hollows between the papillae.

In designating the epidermis as a secretion from the dermis, the absence of organization, except of the lowest grade, would seem to be implied, for its connection with the functions of absorption and exhalation are more physical than vital. The assertion of Breschet and Roussel de Vauzeme, that the epidermis becomes organized like false membranes, gives to the former too high a place in the scale of vitality, which it possesses more in the manner of vegetable than of animal organization. We cannot allow much importance to the assertion of Schultze, that he injected with oil of turpentine a very delicate net-work of vessels, which separated with the epidermis from the true skin, since these vessels may have belonged to the sub-epidermic layer, and have been mechanically torn away. (*Müller's Physiology*, Bell's edition, p. 425.)

The dermis or cutaneous tissue proper consists of an interlacement of fibres, in which secreting organs of different kinds are imbedded. It is composed of elastic and contractile fibrous tissue, which is, also, at the same time areolar, and of nerves, blood-vessels and lymphatics. It is white, and never partakes of the colouring matter of the epidermis. Under it are seen the vessels and nerves which penetrate it, and openings for glandular bodies, and, on its external surface, the dermis assumes a membranous appearance, and is perforated for the passage of the secreting and absorbing apparatus.

The papillae consist, or rather the papillary layer, consists of conical minute prominences, arranged in the palm of the hand and sole of the foot in a regular order, in their being collected into little square masses, each containing from ten to twenty papillae, which are disposed in parallel rows.

The special secretions of which the skin is the seat are, in addition to its chief one, the epidermis, the hair, the sebaceous matter, and the perspiration. Hairs are described to be horny appendages of the skin, or processes of the epidermis, penetrating the dermis. They are produced by the involution and subsequent evolution of the epidermis; the involution constituting the follicle in which the hair is enclosed, and the evolution the shaft of the hair. The producing organ of the hair consists of a pulp analogous to a papilla of the dermis, and is the organ whence the hair is produced,—in a manner identical with that of the formation of the epidermis by the papillary layer of the dermis. The colour of the hair, like that of the epidermis, is due to the presence of pigmentary granules contained within the cells. The sebaceous glands are minute branched follicles, imbedded in the substance of the dermis, and often by orifices distributed over its surface. They terminate for the most part in the follicles of the hairs. In the scalp there are two of these glands to each hair follicle. Sebaceous glands are met with in all parts of the body, but are most abundant in the skin of the face, and in those situations which are naturally exposed to friction.

The sudoriferous glands have been already mentioned (Note to p. 25). They are formed by small tubes of peculiar construction, which are spread over the whole surface of the body, and pour out their

secretions by minute pores in the epidermis. Both the sudoriferous and the sebaceous glands are lined by an inversion of the epidermis.

The nails are horny appendages of the skin, identical in formation with the epidermis and hair, but peculiar in their mode of growth. A nail is implanted by means of a root in the fold of the dermis, which acts the part of a follicle to the nail. At the bottom of the groove of the follicle are situated a number of filiform papillae, which produce the margin of the root, and, by the successive production of cells, push the nail onwards in its growth. The papillary structure of the dermis, which produces the nail, is continuous around the circumference of the attached part of that organ with the dermis of the surrounding skin, and the horny structure of the nail is, consequently, continuous with that of the epidermis. For farther details on the minute anatomy of the skin, see Erasmus Wilson's *Practical and Theoretical Treatise on the Diagnosis, Pathology, and Treatment of Diseases of the Skin*, &c.; also, *Nouvelles Recherches sur la Structure de la Peau*, by M. G. Breschet and M. Roussel de Vauzeme; and *Comparative Anatomy of the Skin of Man, the Domestic Animals, &c.* (*Vergleichende Untersuchungen*, &c.) By Professor Gurlt, in *Müller's Archiv*. A good notice of these two last-mentioned works will be found in the second volume of the *British and Foreign Medical Review*.

If we inquire into the general anatomy of the skin, we discover that this tegument is continuous with the system of mucous membranes, to which it bears a close resemblance, and with which, as some allege, it is actually identical. One important difference, however, presents itself, in the proximate organic principle which constitutes the basis of structure: that of the dermis being almost entirely gelatin, whereas, the basis or proper texture of the mucous membrane is albuminous. In the superadded structures, as of epithelium of the mucous membranes, corresponding with the epidermis of the skin, and in the distribution of blood-vessels, lymphatics, nerves, and glandular bodies or follicles, and in the double series of functions, viz., 1, absorption and exhalation, placing them under the domain of organic life; and 2, sensibility and impressibility to temperature and to the physical properties of matter, connecting them with animal life, there is a close resemblance. The sympathies between the two orders of teguments are active and numerous, both in health and in disease, and they are influential as well in the pathology as in the therapeutics of diseases of the skin.

From the skin carbonic acid and nitrogen are exhaled, as they are from the mucous membrane of the lungs; and from both is discharged a vapour, which, when condensed on the former membrane, with salts, &c., constitutes sweat, and, on the latter, water, with some animal matter. The secretion from the sebaceous follicles of the skin, is paralleled by that from the mucous follicles of the respiratory and digestive membranes.

By the process of absorption, gaseous and fluid matters and notably oxygen gas and water, find entrance through the skin into the general system; as this gas and watery vapour do through the mucous membrane of the lungs. So, also, nearly all the articles of the materia medica may be introduced through the skin into the circulation, and produce their distinctive effects on the several organs, in the same manner, though with less certainty of operation, as when they are applied to the digestive mucous surface.

Analogous depurative functions are performed by the skin and kidneys; and the one sometimes compensates, by its increased activity, for the torpor or suspended action of the other. From both organs are largely secreted water and saline matters, and, in less degree, lactic acid. When the urine is secreted in excessive quantity, as in diabetes, the skin is dry. In hot seasons, and in warm climates, the urinary secretion is less abundant, the cutaneous secretion more so: in winter, the reverse is the case; and, in diseases, the same alternation of action is observed.

The reciprocal influence exerted on each other by the skin and digestive mucous membranes, constitutes a most important part of the study of the pathology of cutaneous diseases. Eruptions of various kinds are not unfrequently a result of crude and irritating ingesta; and those of an acute and febrile character are almost always preceded by derangement of the primæ viæ, and particularly of the mucous membrane of the throat and stomach. So, on the other hand, extensive inflammation of the skin, by arresting its secretion, is fol-

lowed by inflammation of the mucous membranes. Extensive burns have given rise to inflammation of the respiratory and digestive mucous membranes, but in a more particular manner to that of the duodenum. In exanthematous diseases, in which a morbid matter is secreted by the skin, the danger of the superposition of internal inflammation becomes more imminent, not merely in proportion to the suppression of the process by which the morbid matter is eliminated from the blood, but also in proportion to the violence of the inflammation by which the function of the skin is arrested. (*Müller's Physiology, edit. citat.*, p. 459.)

Between the effects, on the skin, of physiological and pathological excitement of parts with which it sympathizes, there is this difference, that while the former is followed by a diminished action of the skin, the latter is most generally succeeded by corresponding, if not identical excitement, or increased and morbid action of this tegument. The therapeutical inference is, that, while we may hope to abate and remove some diseases of the skin, consisting in morbid afflux and congestion, by purging and diuretics, there will be a risk of aggravating them by irritants, which, regarded sometimes as pretended specifics, would light up phlogosis of the digestive mucous membranes.

In its physiological conditions, as of heat and coldness, dryness and moisture, fulness or shrinking, we know that the skin is greatly modified by the nervous system, according as the latter is excited, depressed, or otherwise disturbed. That the prolonged operation or frequent alternation of some of these states will contribute to the production, or, where they are present, to the exasperation of some cutaneous diseases, we can readily imagine, *a priori*, even if direct facts were wanting.

In the *etiology* of cutaneous diseases, we study the causes which act directly on the skin itself, or indirectly, by some organ with which it sympathizes, or through the blood and nervous system, and in this way on the constitution generally. Of the first of these causes, various external irritants, beginning with seasons and climate, and coming down to artificial heat and uncleanly habits, stand out most conspicuously. *Lichen tropicus*, or prickly heat, is a familiar example of the effect of high temperature in causing cutaneous disease, as is *erythema intertrigo* of that of cutaneous friction, and pityriasis or scurf by the repeated friction of the razor on the chin, and sometimes of a rough comb or hard brush on the hairy scalp. In illustration of the occurrence of secondary or sympathetic irritation transmitted from another organ, causing eruption and morbid alterations of the skin, it will be sufficient to mention *urticaria ab ingestis*, or nettle rash from certain kinds of food, particularly shell fish, and *rosacea* from gastro-enteritis. To the same purport, we may cite *strophulus* or red gum, as resulting often from the irritation of teething. The most distressing and remarkable example of cutaneous disease caused by a deprivation of the blood and constitution generally, is in the *syphilides*, or syphilitic eruptions. As is stated by the author in the text:—"In the epidemic syphilis of the 15th and 16th centuries, venereal eruptions occurred so commonly a short time after infection, that the disease was regarded as a *contagious affection of the skin*." From a similar cause, or general constitutional deterioration, come cutaneous scrofulous tubercles.

The question of the hereditariness of certain cutaneous diseases, or at least of strongly inherited predispositions to acquire them, presents itself naturally to the mind of the practitioner. He will find that *acne*, *sycosis* and *porrigo* having occurred in the parents, are very apt to show themselves in the children at an age, and during a period nearly identical with those in which the former had been affected (Plumbe, *A Practical Treatise on Diseases of the Skin &c.*, p. 29, Am. Edit.) *Ichthyosis*, or fish skin disease, has not only been transmitted from parent to child for several generations, but is at times congenital. *Pellagra* has been often observed to appear in those whose parents had suffered from the disease.

Very little reflection must soon convince us, that a knowledge of the causes and connections of many cutaneous diseases, will not a little influence us in our therapeutical views. Thus, for example, when the eruption depends on the irritation of teething, we can have but little hopes of its entire removal, until the process of dentition is completed; nor shall we feel inclined to harass the little patient by various remedies, but wait patiently for the period of irritation to pass,

and with it the sustaining cause of the disease. When, again, we encounter a cutaneous eruption sustained by gastric or by gastro-intestinal irritation, we direct our remedies to this latter morbid condition as to the source of the malady. So, in eruptions depending on constitutional cause we cannot hope for, and ought not to promise, their entire removal until time is allowed for the operation of appropriate remedies, to alter the state of the blood and constitution. This is eminently the case in syphilitic and scrofulous eruptions, and in *pellagra*, and it may be added in a majority of cutaneous diseases. The eruption is properly but a symptom, or at any rate not more than a part of the entire disease.

**CLASSIFICATION OF CUTANEOUS DISEASES.** On this point, the author has detailed the views of his predecessors by which they were guided in their arrangement. Willan, it was stated, followed Plenck in founding his on the external characters of the diseases of the skin when at their acme or height. Plumbe gave his arrangement as "founded on the constitutional causes of the disease, and due consideration of the organic structure and physiology of the part of the skin on which it is seated." It is doubtful if more than an approach to an anatomical basis can be made in the present imperfect state of our knowledge of the several parts of the cutaneous tegument affected in the different eruptions. Reference has been already made, in notes, both by the author and translator of the present work, to Dr. Craigie's distribution of diseases of the skin upon anatomical grounds. It merits more notice than in these passing allusions merely; and as the work containing it (*Elements of General and Pathological Anatomy*) is in the hands of few readers in this country, the American editor believes that he will enhance the value of these "outlines" by introducing it in this place, accompanied by part of the author's commentaries on the several preliminary definitions. Dr. Craigie points out the fact, that Bichat, after the example of Cullen, attempted to distinguish cutaneous diseases according to their seat in the cutaneous tissue. This method, he adds, is obviously the most rational, and has received the approbation of such observers as Meckel and Beclard. The different seats of cutaneous inflammation are briefly stated by Dr. Craigie, as a kind of introduction to his arrangement:

"Cutaneous inflammation, though it eventually affect the substance, which, however, is not frequently, may be conveniently distinguished in the following manner. *First*, it may be seated in the exterior or cuticular surface of the corion; *secondly*, it may affect the *papillæ* or minute elevations of the corion; *thirdly*, it may affect the substance of the corion; *fourthly*, it may occur at the inner or attached surface of this membrane. If these circumstances be adopted as the basis of general division, subordinate characters may be derived from the mode in which the inflammatory process advances, and from the effects which it produces, in the following order:—

**DIFFUSE OR SPREADING INFLAMMATION.**—I. Cutaneous inflammations seated in the outer or cuticular surface of the corion, (*cutis vera, derma*), and generally spreading along it.

Measles,	Rubeola.
Rash fever, scarlet fever,	Scarlatina.
Nettle-rash,	Urticaria.
Rose-rash,	Roseola.
Common rash,	Erythema.

**EFFUSIVE INFLAMMATION.**—II. Cutaneous inflammation seated in the outer surface of the corion, producing a fluid which elevates and detaches the cuticle.

Rose, St. Anthony's fire,	Erysipelas.
Bleb fever, bullose fever,	Pemphigus, febris bullosa.
Simple blebs,	Pompholyx.

**PUNCTATE PAPULAR INFLAMMATION.**—III. Cutaneous inflammations commencing in circumscribed or definite points of the corion, producing minute eminences.

Gum, gown, red gum, tooth gum,	Strophulus.
Sun-rash, prickly heat,	Lichen.
Itchy rash,	Prurigo.

**PUNCTATE DESQUAMATING INFLAMMATION.**—IV. Cutaneous inflammations of the outer surface of the corion, more or less circumscribed, affecting its secreting power, and producing exfoliation of the cuticle.

Scaly leprosy,	Lepra.
Scaly tetter,	Psoriasis.
Dandriff,	Pityriasis.
Fish-skin disease,	Ichthyosis.

**PUNCTATE VESICULAR INFLAMMATION.**—V. Cutaneous inflammations originally affecting the outer surface of the corion, circumscribed, definite, or punctate, producing effusion of fluid, first pellucid, afterwards slightly opaque, with elevation of cuticle, with or without further affection of the corial tissue.

Miliary rash,	Miliaria.
Shingles, vesicular ringworm, or fret,	Herpes.
Heat spots, or red-fret,	Eczema.

Limpet shell vesicle and scab,	Rupia.
Cow-pox vesicle,	Vaccinia.
Chicken-pox,	Varicella.
<b>PUNCTATE PHLEGMONOUS OR PUSTULAR INFLAMMATION.—VI. Cutaneous inflammation originally affecting the outer surface of the corion, afterwards its substance, and producing purulent matter more or less distinct.</b>	
Small pox,	Variola.
Plague,	Pestis.
Mal-gouti pustule, Persian fire,	Anthraxion.
Itch,	Scabies.
Moist or running tetter,	Impetigo.
Scall or pustular ringworm,	Porrigo.
Great Pox,	Echyma.
<b>PUNCTATE CHRONIC PHLEGMONOUS INFLAMMATION.—VII. Cutaneous inflammations originating in the substance of the corion, sometimes at the bulbs of the hair, and terminating in partial or imperfect suppuration, with formation of scales, crusts, &amp;c., and more or less destruction of the corial tissue.</b>	
Boil,	Phyma, furunculus.
Carbuncle,	Anthrax Carbunculus.
Wheal,	Acne.
Scalp or chin wheal,	Sycosis.
Canker,	Lupus, noli me tangere.
White scall,	Vitiligo.
Yaws,	Framboesia, rubula.
Sivveds,	Sibbenia.
<b>PUNCTATE PHLEGMONOUS-TUBERCULAR INFLAMMATION, CHRONIC.—VIII. Cutaneous inflammations, chronic, attended with general affection of the fibro-mucous tissue.</b>	
Arctic leprosy, radesyge,	Lepra Norwegica.
Lombard evil, pellagra,	Pellagra.
Scherlievo, Falcadina,	Lepra Piedemontana.
Asturian itch or scab, Mal di Rosa,	Lepra Asturiensis.
Crim evil, Krimmische krankheit,	Lepra Taurica.
Arabian leprosy,	Elephantiasis.
Soft tubercle.	Molluscum.
Wari,	Verruca.

"a. *Cutaneous inflammations seated in the outer or cuticular surface of the corion, and generally spreading along it.*—Inflammation of the outer surface of the corion may be diffuse and continuous, as in scarlet fever, diffuse and interrupted, as in common rash (*erythema*), nettle-rash and rose-rash, or diffuse and of determinate figure, as in measles. The redness with which superficial cutaneous inflammation is attended varies. Though it disappears on pressure, it returns immediately. In scarlet fever, though its tint is indicated by the name, it often has a shade of brown; in *erythema*, or simple rash, it is rarely so vivid as in other forms of cutaneous inflammation; in rose it has a tinge of yellow. In measles it assumes the shape of crescentic or lunular patches. In simple rash it terminates gradually in the sound skin; but in one variety of this rash (*erythema marginatum*), and in rose it is marked by a distinctly circumscribed edge, or is said to be *marginate*. The swelling of superficial cutaneous inflammation is rather a general distension than obvious elevation. When it is obvious to the eye, or felt by the finger, and is at the same time confined to definite red patches, these are named wheals. A familiar instance of this occurs in the effect produced by the bite of several insects, the blow of a whip, or the stinging of nettles. Spontaneously it is seen in the disease named nettle-rash. In rose, elevation, extensive and continuous, conterminous with the redness, and like it bounded by a distinctly circumscribed edge, is uniformly observed.

"Superficial cutaneous inflammation being seated in the extensive vascular net-work, (*rete vasculorum, reseau vasculaire*), of the corion, always destroys to a greater or less extent its scarf-skin, which comes away in small portions or scales, sometimes in larger pieces, while a new but thinner and more transparent scarf-skin is formed. The process by which these changes are effected is termed desquamation, and is observed in measles, scarlet fever, nettle-rash, rose-rash, common rash, and rose when it does not proceed to the formation of blebs. As the process thus defined forms a good mode of distinguishing its varieties when seated in the outer or cuticular corial surface, I adopt it on the present occasion.

"According to the definition above given, it comprehends the following diseases:—Measles, rash fever, scarlet fever, nettle-rash, rose-rash, common rash.

"b. *Cutaneous inflammations situate chiefly in the outer surface of the corion, producing sero-albuminous fluid, which elevates the scarf-skin into pushes, blebs or blisters, (Bullæ, Phlyctenæ), commencing in certain parts of the corion, but spreading continuously.*

"The outer surface of the corion may be inflamed in such a manner as not to terminate in desquamation or resolution, but to pour forth a

watery yellowish fluid, which detaches the cuticle and elevates it in the form of a bleb or blister. This is very well seen in the instance of scalding by boiling fluids, on the application of the blistering fly (*Meloe vesicatorius*), or even in some cases of friction of parts naturally tender. In each of these cases, in a short time large watery elevations or bladders appear. The same process takes place spontaneously in rose, in common blebs and in the bullose or bleb fever. The form of these blebs is not determinate; nor even are they always uniform in appearance. The action by which they are produced, though more violent in degree, is not different in kind from ordinary cutaneous inflammation. It is attended, nevertheless, with more swelling of the corion, more exquisite burning heat, and more searing or scalding pain, than the other forms of superficial cutaneous inflammation. The fluid secreted by this process is sero-albuminous. When the raised cuticle is divided, a yellowish transparent watery fluid escapes; and when the cuticle is detached so as to expose the inflamed spot, the inflamed skin is found covered by a quantity of soft, cellular, gelatinous matter, of a yellow-white colour, somewhat tough and similar to coagulable lymph. This substance is traversed by firm linear partitions, not uniform in number or direction, but forming interstices from which serous fluid, the same as that which escaped first, is discharged. The coagulable matter, which is albuminous, at the same time contracts, and forming a covering to the corion, while the latter begins to secrete a new cuticle, is at length thrown off in the form of opaque patches. These facts show that the new secretion, though discharged fluid, afterwards separates into a serous and an albuminous portion, and is an imperfect or modified coagulable lymph; that both are the product of the inflammatory process; and that the latter is analogous to that producing albuminous exudation from serous membranes. This analogy has not escaped Bichat, who remarks, that vesications do not occur in the latter, solely because they want epidermis. To this head belongs the inflammation of cutaneous whitlow.

"c. *Cutaneous inflammation commencing in circumscribed or definite points of the outer surface of the corion, and producing minute eminences or pimples (papulæ), which disappear gradually or terminate in scarf, or minute exfoliations of the cuticle.*

"When cutaneous inflammation appears in the form of innumerable minute points, which, without spreading or coalescing, remain in general distinct, it differs in nature from that which has been already considered as the spreading or diffuse inflammation. The simplest form under which this is observed to occur is that which consists of the minute pointed elevations named pimples (*papulæ*), which may be described as small conical eminences, surrounded by a red circle, and sometimes attended with superficial redness of the neighbouring skin, but without definite figure. They are slow in progress, do not proceed to suppuration, and after remaining an uncertain time, subside gradually, occasioning a branny or scurfy exfoliation of the scarf-skin with which they are covered.

"These seem to have been the circumstances which induced Dr. Willan to consider pimples as arising from inflammation of the *papillæ* or conical eminences of the corion. I cannot say that personal observation has enabled me to determine whether this is at all times truly the case or not; and I therefore will not positively deny the accuracy of the opinion. On this point, however, I remark,—that I have seen and daily see instances of *strophulus*, in which the papular eruption can neither in form nor distribution be traced to the cutaneous papillæ; that the eruption of *lichen* in adults appears in situations in which the papillæ are few, as regularly and abundantly as in those in which they are numerous; and that we meet with local examples of papular eruption in which it is difficult to suppose the disease to be an affection of the papillæ of one region of the skin only. For these reasons it may be justly doubted whether in all instances papular eruptions consist in inflammation of the papillæ.

"Of the anatomical characters of pimples, little is accurately known. They are not diseases necessarily fatal; and when death takes place during their presence, their distinctive characters are either much changed, or entirely gone before the anatomist can inspect them. In some instances of *strophulus* in infants cut off by other diseases, I have seen the corion rough and slightly raised in irregular spots, which were the seat of closely-set pimples during life.

"d. *Cutaneous inflammation of the outer surface of the corion, more or less circumscribed, affecting its secreting power, and thus producing first, exfoliation of the scarf-skin, afterwards vitiated scarf-skin.*

"Though the scarf-skin (*cuticula, epidermis*), and nails are incapable of injection, and are therefore believed to be inorganic, the former is remarked to be more sensible when thin and semitransparent, than when thick and opaque, which it may be in certain regions. It is also observed, that when it is removed by a blister, or the effect of a scald, the surface of the corion, when it ceases to discharge the sero-albuminous fluid already noticed, becomes covered by a thin pellicle of transparent membrane, so delicate that it affords very little defence to the subjacent skin. This same transparent pellicle is observed in the skinning or cicatrization, as it is named, of cutaneous wounds. If, under these circumstances, the formation of this pellicle be observed, it will be found that it is deposited from the outer or cuticular surface of the corion, like a secreted substance in a viscid or semifluid state, and afterwards becoming hard, dry and semitransparent.

"When the outer surface of the corion becomes inflamed or otherwise disordered, its secretion is no longer performed with the same perfection or regularity. The effect of this is seen in the vitiated state of the scarf-skin, which is no longer the uniform, continuous, firm, semitransparent membrane observed in health, but becomes broken, thickened, opaque and divided into numerous scales. Of the various modes in which this secretion may be deranged, and of the varieties in cuticular disease to which it may give rise, too little is known to speak with precision of their individual forms. But it may be considered as certain, that every morbid state of the outer surface of the corion gives rise to certain unnatural conditions of the cuticle, and that every anormal state of the cuticle depends originally on a morbid state of the cuticular or secreting surface of the corion. In general, this morbid state consists in some degree of inflammation, or at least it is attended with some degree of this process, though in the chronic form. In some instances, this chronic inflammation is obviously the immediate cause of the derangement of secretion; but in other instances, the disordered secretion continues after the inflammation subsides. The former is observed in the Greek leprosy (*lepra*), and the scaly tetter (*psoriasis*), in both of which the formation of the morbid opaque scales is preceded and attended by a red inflamed state of the corion taking place in minute spots. It is less obvious in dandriff (*pityriasis*), in which the surface of the corion, though dry, harsh and rough, is not particularly red or vascular, and which, therefore, appears to exemplify the latter statement. The fish-skin eruption (*ichthyosis*), is in general so chronic that it is difficult to say whether it is or is not attended with any degree of the inflammatory process; but when its commencement can be traced, it is generally possible to recognize marks of inflammation of the outer surface of the corion.

"e. *Cutaneous inflammation originally affecting the outer surface of the corion, circumscribed, definite or punctuate, producing effusion of fluid, first pellucid, afterwards slightly opaque, with elevation of cuticle, with or without further affection of the corial tissue.*

"Inflammation may be developed in many minute points of the corion simultaneously, and, continuing limited to these points without spreading, may terminate in each in the formation of a pellucid fluid, afterwards becoming more or less opaque. These may either be confined to the outer surface of the corion, without affecting its substance, or, beginning originally at the surface, may thence affect its substance.

"The individual points appear first like a common rash, with general redness of the skin, sometimes like pimples or minute elevations, with a good deal of redness surrounding them. After some hours, a white pearly point appears at their summits, while the surrounding redness diminishes in breadth, so as to form a mere circle or hoop (*areola*), which, if minutely examined, is found to consist of a zone of vessels, circumscribing the inflammatory process, and forming in their centre the fluid which gives the elevation the white appearance. After 12, 20 or 30 hours more, according to circumstances, the white pearly appearance extends, assumes a tint of yellow, and is depressed on the summit, indicating the advancement of the process of circumscribed inflammation. In the course of two

or three days, there is detached a thin crust or scab, which consists of the cuticle of the part with the dried fluid adhering to it. Minute elevations of this description have been termed vesicles (*vesiculae*), and the contained fluid *lymph* by Dr. Willan. The fluid thus distinguished is not the same as the coagulable lymph of J. Hunter. It is nevertheless sero-albuminous, and appears to be quite similar to that which is secreted in the first stage of suppuration. The process by which it is secreted is confined to the vascular surface of the corion, and is not attended by ulceration of that surface in millet-rash, shingles (*herpes*), and the red-fret or mercurial eruption (*eczema*). In chicken-pox it is sometimes attended by ulceration of the corial surface, sometimes not.

"In the other two forms of vesicular inflammation, though the process commences at the surface of the corion, it finally affects the substance of that membrane.

"In the limpet-shell vesicle (*rupia*), inflammation of the punctuate or circumscribed character commences in one or more points of the outer surface of the corion, and causes the secretion of a thin clear fluid, which first elevates the cuticle into a broad flat vesicle, and soon becoming opaque, oozes through the broken cuticle, and is hardened into thin, superficial, but in general, laminated scabs. These vesicles are surrounded by a red, hard and painful margin or base, indicating slow inflammation of the corial tissue.

"The progress of this form of cutaneous inflammation, demonstrates clearly and satisfactorily the gradual transition of the morbid action from the surface to the substance of the corion. The inflammation, confined at first to a small spot by the usual zone or areola, causes merely sero-albuminous secretion, and consequent elevation of the cuticle. If at this time the cuticle be removed accidentally or intentionally, the subjacent surface of the corion is intensely red, soft or velvety and pulpy, elevated and extremely tender, while the surrounding ring or hoop of skin is hard, and equally elevated and red. From the softened inner portion the secretion of sero-albuminous fluid, generally of a reddish tint, continues; and the surface itself begins to become rough, and to lose its velvet aspect. This indicates incipient ulceration, which proceeds to affect the substance of the corion, until it is either much or wholly destroyed, generally in the form of an inverted cone; while the place of the destroyed skin is supplied by the sero-albuminous secretion, which hardens as it is formed, and seems thus to sink deeper and deeper into the skin. In the meanwhile the surrounding portion of the skin is much indurated and inflamed, and seems to form a hard ring in the skin; and the whole process is attended with extreme pain, searing heat, and constitutional distress. These phenomena are most distinctly seen in the *rupia prominens* and *escharotica*, and in a variety of the eruption, which I have witnessed in the persons of those who have been affected with the constitutional symptoms of syphilis, and who have for this been subjected to repeated courses of mercury (*rupia cachectica*).

"Cow-pox (*vaccinia*), whether in the teat of the cow, or the skin of the human subject, consists in local inflammation of the outer surface of the corion, which, by causing the secretion of a thin semitransparent fluid, elevates the cuticle into a vesicle. At the same time, the surrounding skin is red, sore and hard (*areola*); and the inflammatory process denoted by these signs causes suppuration of the corion, with some destruction of its substance, or what is termed ulceration.

"If the thin fluid secreted by the vaccine vesicle either in the teat of the cow, or in the skin of the human subject, be taken before it has become opaque or puriform, and applied to the surface of the human corion exposed by scratching, slight incision, or suitable abrasion of the cuticle, it is followed by local inflammation of the same characters as those of the original sore or vesicle, from which the morbid fluid is taken. The vaccine inflammation is naturally divided into two stages."

"During the progress of the local inflammation, some disorder of the constitution takes place generally about the seventh or eighth day, in the form of loss of appetite or sickness, slight thirst and heat, and dryness of the skin. The pulse is almost never affected. The vaccine vesicle may also produce sundry cutaneous inflammations, very transitory, and of a secondary nature. Of these the vaccine rose-rash (*roseola vaccina*) is the most important and frequent.

"It must not be understood that vaccine fluid, when applied to the human body, ever produces a general eruptive disease like itself over the person. This, indeed, was believed to be the case at first by Jenner, Pearson, Woodville, and perhaps some others. But more correct knowledge of the history of the disease shows that its action is confined to the identical spots to which it is applied; that these, and these only, become the seat of genuine vaccine inflammation; and that whatever eruptions or other morbid changes in the skin succeed, or have been said to succeed, the communication of cow-pock to the human body, are not the result of its genuine or proper action. It is strictly and truly a local morbid process."

"Of *chicken-pox* as a cutaneous inflammation sometimes affecting the corial substance, I have already merely spoken. Like instances of the punctuate inflammation, though it commences at the surface of the corion with sero-albuminous secretion, it very often proceeds to suppuration, and occasionally affects the corial tissue. This is seen in the lenticular and more distinctly in the conoidal chicken-pox, in which the suppurated points are marked by depressions. The cutaneous punctuate inflammation of chicken-pox may be considered as the link which connects the vesicular and the pustular eruptions.

"The facts now adduced show that it is impossible to draw a distinct line between the vesicle and the pustule, as was attempted by Willan and Bateman. Looking only at the pathological process by which they are developed and advance to maturity, it is more natural to consider them as differing in degree only, and as gliding by imperceptible shades into each other, than as always capable of being accurately distinguished. What is a vesicle, when first observed, may assume the appearance of a pustule on the following day; and the thin sero-albuminous fluid, by which they have been supposed to be distinguished, may be converted into purulent matter before the termination of the disease. As the terms, nevertheless, are useful as precise distinctions in nomenclature and description, and as they occasionally may be traced to a pathological difference, I retain them in the present observations.

"*f. Cutaneous inflammation originally affecting the outer surface of the corion, afterwards its substance, and producing purulent matter more or less perfect.*

"Inflammation of the minute circumscribed kind, though commencing originally on the surface, may speedily affect the substance of the corion, and in its progress may produce more or less loss of substance, with formation of purulent matter. The objects thus formed are named *pustules*, and are to be viewed as instances of genuine phlegmonous or rather purulent inflammation of the skin. Practical authors enumerate four forms under which this species of cutaneous inflammation may take place:—1st, the *psyracium*; 2d, the *achor*; 3d, the *favus*; and 4th, the *phlyzacium*. To this number I feel it necessary to add the *phlyctidium*.

"The *psyracium* may be viewed as the connecting link between the vesicle and pustule. It is small, often irregularly circumscribed, producing but slight elevation of the cuticle, and terminating in a laminated scab. It is attended with little or no redness of the surrounding skin (*areola*), does not affect the corion deeply, and rarely almost never leaves a hollow scar. Several of them often appear together, and becoming confluent after discharging the scanty puriform matter which they furnish, pour out a thin watery fluid, which on drying forms an irregular incrustation.

"The *achor* differs not much from the *psyracium*. It appears in the form of a minute pointed elevation, of a yellow-colour, and succeeded by a thin brown or yellowish scab. It contains straw-coloured matter of the appearance and consistence of strained honey; it is surrounded with little inflammatory redness, and seems to affect the corion as little as the *psyracium*. In ordinary circumstances it leaves no scar.

"The *favus* may be esteemed the next degree of inflammation of this tissue. It is larger and flatter than the last-mentioned pustule, not pointed, and contains a more viscid matter than the *achor*. It is surrounded by a slight-red, irregular, marginal ring, indicating a more considerable affection of the corial tissue. It is succeeded by a yellow, semitransparent, and sometimes cellular scab, like honeycomb.

"A form of pustule referable neither to these, nor to that which is to follow, I must here mention,—the *phlyctidium* or genuine small-pox

pustule. It consists in a circular or annular spot of inflammation of the corion, encircled by a red ring or zone, which is observed to consist of the outer corial surface, highly vascular and elevated. Within this suppuration takes place. Though the *phlyctidium* is observed spontaneously in the distinct small-pox, it is also produced artificially by friction of tartar-emetic ointment.

"The *phlyzacium* is the most perfect example of the most violent degree of this form of cutaneous inflammation. It is described as a large pustule, raised on a hard circular base, of a lively red colour, and succeeded by a thick, hard, dark-coloured scab. It is generally slow in progress, and, commencing at once on the surface and in the substance of the corion, is attended with considerable surrounding inflammation; and the suppurative process which follows is always accompanied with more or less destruction of the corial tissue. It often leaves a hollow scar. The surrounding redness, hardness and elevation; the slow progress and sometimes tedious suppuration; and lastly, the loss of corial substance, are the circumstances which indicate the peculiar seat of this form of cutaneous inflammation.

"Into the pathological characters of the individual pustular inflammation the limits of this treatise do not permit me to enter. On one or two of them, however, I shall offer a few remarks which may tend to illustrate the general nature of cutaneous pustular inflammation. I begin with small-pox as one of the most interesting."

"The most doubtful point of this account (*a*) [by Cottugni], of the variolous inflammation, is that which relates to the disease being entirely confined to the mucous body of Malpighi. The existence of this membrane is very doubtful, and if it cannot be demonstrated, the opinion of small-pox being confined to it is obviously inconclusive. If the term *outer surface of the corion* be substituted for mucous body, the whole description may be regarded as not far from the truth. The depressed pit or *navel* of which Cottugni speaks, corresponds with the central slough of John Hunter, to which I shall advert in its proper place. At present, the process of variolous inflammation, if divested of hypothetical language and opinions, may be stated in the following terms:—

"The small-pox eruption consists of circumscribed points of inflammation developed simultaneously in many spots of the corion. These inflamed spots (*phlyctidia*), always commence at the cuticular or outer surface, and in general penetrate to a depth which is greater or less in different circumstances. After no long time, each *phlyctidium* is surrounded with a hard, red circle, somewhat raised, which may be conceived to indicate the process of cutaneous inflammation. Hunter would say, and perhaps did say, that this inflammation is of the adhesive kind, and arises from lymph effused into that part of the corion which is red, hard and swelled. I believe it cannot be in every instance shown that this hard swelling depends on effusion of lymph; and it may be doubted whether it arises from such effusion in the case of small-pox. *First*, hardness and swelling take place at a period of the eruption so early, that it appears unreasonable to ascribe them to effused lymph. *Secondly*, hardness and swelling accompany every example of circumscribed or definite inflammation. *Thirdly*, it is not easy to understand in what particular part the lymph could be effused, for the corion does not contain cells or cavities like the filamentous tissue, but the outer surface consists of a smooth dense membrane, abounding in minute blood-vessels. *Fourthly*, it is as easy and more natural to think that if effusion took place, it would do so into these minute vessels. In point of fact, the capillaries of the corion of the pustular redness and hardness are numerous and distended; and we believe that the truest conclusion is, that the redness, hardness and swelling of each pock, consist in the unusual distension of the corial capillaries with blood.

"Pustular inflammation of the skin naturally terminates in suppuration, which may be either with or without destruction of the corial tissue. In the variolous *phlyctidia*, when distinct, destruction of the skin is rare, but may occur. There is reason to infer that it takes place in consequence of a true process of ulceration."

"From these facts and observations, [after Hunter, Adams and

(a) It is not deemed necessary to repeat here the description by this author, as given by Dr. Craigie.

Cruikshank,] as well as those which it has occurred to myself to make, the following conclusions may be drawn:—

"The *phlyctidium* or pustule of small-pox consists of a cutaneous inflammation, which may produce,

"1st. Secretion of puriform fluid without permanent injury or destruction of the corion. In lenticular chicken-pox, and distinct small-pox, there is no doubt that though suppuration takes place from the cuticular surface of the corion, it is not necessarily connected with destruction or ulceration of that membrane.

"2d. Suppurative ulceration of the corion. In conoidal chicken-pox, in some instances of distinct small-pox, and in many instances of small-pox partially or wholly confluent, each pock goes on to ulceration of the corion. It does not appear that the pock slough described by Hunter is present in every case. It is admitted by Adams to be wanting in the vesicular small-pox, which appears after cow-pox, and in some other occasions.

"3d. Death of numerous spots of the corion constituting sloughs. In some cases of distinct small-pox this has been observed; but it is most frequent in the confluent eruption. It then appears in the form of a white circular patch lying at the bottom of each pock.

"4th. Along with sloughs at individual points, an extensive spreading redness of the skin rapidly terminating in sloughs of irregular shape and limits not unfrequently occurs in certain bad forms of variolous eruption."

"Of the diseases termed *malignant pustule*, by the French and other foreign authors, (*Anthraxion*; Nar al-Parsi; *Persian fire*), we can scarcely speak from experience in this country, in which, so far as I am aware, the disease is unknown. From the description given by Enaux and Chaussier, Vicq-d'Azyr, Pinel, Ozanam and others, it appears to consist in inflammation of the outer surface of the corion, speedily depriving that membrane of its vitality. It may commence in one or two modes; *first*, as a hard, red, burning, not elevated point, speedily causing bluish or reddish-blue fluid secretion, elevating the cuticle into a purple or pale blue blister (*phlyctæna*); *second*, as a hard knotty substance slightly elevated into a doughy swelling, and causing detachment of the cuticle by similar effusion. In both cases the affected corion undergoes mortification partial or general, and is then detached as a foreign body. In some respects this resembles the ordinary carbuncle of this country. But it differs particularly in this, that the malignant pustule (*anthracion*), is ascribed by the best authorities to contagion, and very often is traced to epizootic contagion, or pestilence occurring among the lower animals.

"The great pock (*ecthyma*) consists in an eruption of red, hard, sore pustules (*phlyzacia*), distinct, seldom numerous, without primary fever, and not contagious. In the three species of ordinary (*E. vulgare*), infantile (*E. infantum*), and dingy pock (*E. luridum*), the pustules are round or oval hard masses fixed in the substance of the skin, which is red, hard and swelled, and terminating first in elevation and desquamation of the cuticle, and then in imperfect softening, discharging a serous and generally blood-coloured fluid, which concretes into a foul dark-brown or reddish scab, which at length drops off, leaving the subjacent skin reddish, and marked by a depressed scar, indicating the affection of the corial substance.

"g. *Cutaneous inflammations originating in the substance of the corion, sometimes at the bulbs of the hair, terminating in partial or imperfect suppuration, with formations of scales, crusts, and occasionally sloughs, and more or less destruction of the corial tissue.*

"The pathological reader may perceive that the last disease which came under consideration forms a preparatory step to those of the present order. The hard phlyzacious pustules, by which it is distinguished, denote a more complete affection of the corial substance than is known to take place in any previous cutaneous inflammation; while the slow, crude and imperfect solution which they undergo, and the discharge of blood-coloured rather than purulent fluid, indicates a variety of the inflammatory process different from those already examined, and approaching to those now to follow. The transition, therefore, if not insensible, is at least natural, to a tribe of diseases of which the general character is inflammation of the corion, which, modified in various ways, gives rise to the varieties of disease referred to this kind. The principal modifying circumstances may be referred either to duration, to circumscription, or to difference in kind.

"1. The influence of duration is observed in the comparative difference of progress of the common boil, which is rapid, and that of the whelk (*acne*), canker (*lupus*), and yaws (*frambæsia*), which are slow and tedious. 2. The influence of circumscription or diffusions is evinced in those inflammations which are confined to a spot, and those which spread to some extent. In the whelk and boil the inflammatory process is restricted to a point; in carbuncle, on the other hand, it affects a great extent of the corion through its entire thickness. 3. Whether the inflammation of the corial substance be different in one disease from what it is in another, there are few means of ascertaining. Though various facts seem to indicate something of this nature, too little is known to justify positive conclusions.

"The boil or bile (*Die Beule*; *Furunculus*; *le Clou*; *il Ciccione*): may be adduced as an instance of acute inflammation of the corion confined to a certain spot. Pearson admits that its seat is the skin; but, by afterwards saying that it may occur in any part which abounds in cellular membrane, leaves the alternative either that skin contains this substance abundantly, or that boils may occur in many other tissues. Boyer, by placing its seat in the cellular tissue, confounds it with phlegmon. The opinion of Bichat differs from either, but partakes of both. This anatomist represents the corion to be penetrated by a great quantity of cellular tissue, which fills its *areola*, and is the exclusive and proper seat of the boil. The truth of this opinion depends on the idea attached to the term *cellular tissue*. If by this be meant the loose fatty matter with its intersecting threads, on which the inner surface of the corion rests, the opinion is erroneous; for this is the proper subcutaneous cellular tissue. To this doubtless the inflammatory action of boil may descend; but the phenomena and termination of the disease show that it consists at first of circumscribed inflammation of the corial substance, soon but slightly affecting the subjacent cellular tissue. The circumstances which indicate the corion as the seat of furuncular inflammation, are,—the defined knotty tumour with which the complaint begins, the minute pustule to which it gives rise, and the imperfect and tardy suppuration with formation of sloughs, and the perforated appearance of the skin.

"Of the same nature are the inflammatory tumours termed epinycitis and terminthus mentioned by all authors almost from Celsus to Wiseman.

"Though in this place I notice carbuncle as an example of spreading inflammation of the substance of the corion, yet the question of its precise seat is not free from ambiguity. Hunter believed it to begin in the skin, and going deeper to affect principally the cellular membrane, of which it caused mortification; and with this Pearson agrees. Boyer places it in the teguments and subcutaneous cellular tissue; while Monteggia, who repeats the fact that it destroys a considerable portion of the teguments and cellular substance down to the muscles, seems to regard it as a peculiar action affecting several tissues simultaneously and successively."

"Upon the whole, it may be concluded that the corion is the primary seat of disease in carbuncle, and that the affection of the cellular membrane, with which it is uniformly accompanied, is the effect of spreading inflammation of the corial tissue.

"The whelk (*acne*; *ionthos*; *varus*, *vari*, Celsus) consists of minute portions of corion, round, oval, or spheroidal, hard, circumscribed and elevated. Of the four sorts enumerated by Bateman, three only, the simple (*A. simplex*), the inveterate (*A. indurata*) and the crimson (*A. rosacea*), can be considered as examples of inflammation of the substance of the corion. The black whelk (*Acne punctata*), doubtless arises from disease and obstruction of the mucous follicles, or sebaceous glands. Both the simple and indurated whelk may produce ulcerative destruction of the true skin, and leave a smooth depressed scar; and I have seen them, by extending to the roots of the hairs, render the skin entirely depilous.

"The crimson whelk (*A. rosacea*, *gutta rosea*; dartre pustuleuse couperose of Alibert), is an affection rather complicated; and I doubt whether it is justly classed with those now mentioned. It is doubtless an affection of the corial substance; but it commences with redness and slight diffuse swelling of the skin of the nose and cheeks, not unlike that of *erythema marginatum*. This is followed by the appearance of two or three small seedy particles, very hard, but red and tending to suppurate, which they at length do partially at their

summits, while the base remains hard, red and firm. As the red appearance of the skin spreads the roughness increases, fresh particles of the same seedy consistence arise and undergo the same course; and some coalescing, form broad tubercular blotches of a crimson or livid colour, and irregular notched surface. The skin is not, however, in this state at all times permanently red. I have seen this affection in patches on the cheeks and nose so light coloured, that in the morning it could not be recognized; but in the latter part of the day, after taking wine, and becoming warm, they assumed an intense red inclining to crimson. In the advanced stage, when numerous tubercles appear, and the surface is generally rough and red, the skin swells diffusely and becomes doughy, and is traversed by tortuous purple veins, the nose is enlarged, the nostrils become distended, their surface notched into lobular masses, the red hard bodies of the cheeks become large and coherent, and the whole countenance is converted into a crimson tumid mass, in which the original features are prodigiously deformed. These wheals do not often undergo suppuration, but are constantly casting the cuticle in the form of peelings, or scales, or crusts. When suppuration occurs it is liable to terminate in bad and intractable sores.

"The chin and scalp wheal (*sycosis, mentagra, dartre pustuleuse mentagré*), consists in chronic pustular inflammation of the substance of the corion at the bulbs or conduits of the hairs. (Celsi, lib. vi. 3.)

"Under the head of canker (*lupus, noli me tangere*, wolf of Wiseman and others, *dartre rougeante*, Pinel and Alibert), may be noticed a disease consisting in hard elevated tubercles set in the corion, from which they appear to grow. The name of *noli me tangere* is applied by Wiseman to a 'small round acuminated tubercle,' without much pain, unless when 'touched, rubbed, or otherwise exasperated by topics.' Though most frequent on the face, it may occur on other parts. One of these, of a bluish colour, and looking like a vein, appears from the description to have been of the nature of erectile tissue.

"One example of bluish spherical tubercle I have seen in the person of a woman of about 65 years of age, otherwise healthy. It was situated on the side of the nose near the middle of the nasal bone. It appeared first in the form of a small red prominence less than a pea, but gradually shot up from the skin, so as, in the course of twenty months or two years from its commencement, to project at least one-third of an inch from the surrounding skin. It was then round or spherical, smooth, and even shining, and of a blue or light purple colour, which, on close examination, was derived from numerous minute vessels. It was connected to the skin by a neck, the base being narrower than the summit, but did not adhere to the bone. What was the ultimate fate of this person I did not learn; but no doubt can be entertained that if life were continued a sufficient time, the tubercle would terminate in destructive fungating ulceration.

"I have seen also many cases of ragged ulceration of the countenance, and one or two in the incipient state before it spread to any extent. One mode in which this disease appears to commence is by the formation of a patch of hard, red skin, slightly but diffusely swelled, and which is the seat of a hot, gnawing, smarting sensation. Though smooth on the surface, it is found by examination to be irregular, or very soon becomes so by the formation of small, hard, round bodies (pustulo-tubercular), which after some time begin to be acuminated, and cast the cuticle in thin peelings. Occasionally they give rise to thin watery vesicles of no determinate shape, which either burst their cuticle and discharge their fluid, or appear to cause an insensible dewy oozing all over the surface. The most usual seat of this form of cutaneous inflammation is the side of the nose, one of the *alea*, or a small portion of the cheek. After subsisting in this form for some time, it may disappear spontaneously, the skin becoming of its natural colour, soft and without pain. More frequently, however, the cuticle continues to be cast off in peelings, vesicles and pustules continue to be formed, and one or other more red and painful than the rest is at length covered by a scab, which, dropping off, discloses a small sore with a smooth ungranulating surface, and a scanty, thin, bloody-coloured, puriform discharge, which generally forms a fresh crust or scab. This either spreads without showing any disposition to heal, or coalesces more or less completely with other sores which are generated in the same mode, and undergo the same process. After proceeding in this manner for weeks or months,

a tendency to heal is manifested in some parts, while others continue to spread. The parts which heal are irregularly scamed and scarred. This form of disease appears to correspond with what Wiseman describes under the name of *herpes exedens*.

"Another form of pustulo-tubercular disease I have seen take place on the skin of the face, generally on the forehead, in the form of round hardish bodies, with flat summits, to the number of eight, ten or twelve, disposed in a circular arrangement. The surface of the skin was red, glossy and occasionally casting cuticular scales and shreds. These bodies were stated to be the seat of an uneasy sensation of heat rather than of pain. They had not advanced to ulceration. Upon removal by the knife, they became pale, white, and shrunk considerably. Internally they consisted of gray-coloured substance, interspersed with a few blood-vessels, not hard, so much as doughy, tough and fibro-cartilaginous. They did not, nevertheless, present the characters of carcinoma, but seemed to consist in an inflammatory induration of the corial tissue.

"On the anatomical characters of the white scall (*vittiligo*), I possess no accurate information. I have often suspected that the appearance referred to this disease are in truth the effects of others more known.

"Yaws (*frambesia*) consist in chronic inflammation of the corion taking place in circumscribed spots, attended partly with death of a portion of the corial substance, partly with growth of granular fungi,—the result of a peculiar morbid poison."

"Not only are yaws an inflammatory disease of the skin, but they are not, strictly speaking, an example of tubercular disease of that membrane, as in the arrangement of Willan is erroneously represented. The phenomena show that they consist in an inflammatory process of the corion commencing in minute points, and gradually spreading in extent and penetrating in depth, till it generates a peculiar morbid product, which, after undergoing certain changes, is at length spontaneously removed, and allows the sore to heal. Thomson justly remarks, that the disease is at first papular, then pustular, and afterwards consists of yaw, though the latter is not constant, as the ulcer may heal without this substance; when it must be accounted pustular. At no period does it appear to be tubercular; for the yawey growth, to which alone this term can be applied, is rather an effect of the pustular or chronic corial inflammation modified by the proper yawey action. It may, in short, be inferred, that when the yawey action is sufficient without being excessive, it generates the proper fungous growths, under which the corion is either not materially injured or is regenerated; if the action be too violent, this growth is either destroyed or prevented from appearing; and in either case the corion is irreparably injured.

"*Sivvens*, though a disease affecting not only the skin, but the fibro-mucous membrane, is entitled to notice in this place, as causing cutaneous inflammation not dissimilar to that of yaws. Like most inflammations depending on the action of a morbid poison, when it affects the constitution, it induces inflammation of the corion in the shape of pustules terminating in bad ulceration and sloughs,—of furuncular tubercles and ulcers,—and of pustular sores affording the raspberry granulating fungus.<sup>1</sup>

"*h. Cutaneous inflammations, chronic, affecting at once the surface and the substance of the corion, and attended with general affection of the fibro-mucous tissues.*

"Of the disorders which I refer to this head, several are so similar, that they are probably to be viewed as varieties of the same morbid action. Of this kind are the Radesyge, Spedalsked, Liktraa or northern leprosy, the Pellagra or Lombard evil, the Scherlievo of the same place in Italy, the Mal di Rosa of Asturia, and a cutaneous disorder prevalent in Crim Tartary. In whatever points these disorders differ, all of them agree in being preceded by distinct febrile commotion, in consisting of inflammation affecting the corion in definite points, and in causing at the same time more or less inflammation, punctuate or diffuse, of the mucous and fibro-mucous membranes of the nasal cavities, the throat, the Eustachian tube, and tympanal cavity.

<sup>1</sup> Gilchrist in Essays and Observations, Phys. and Lit., vol. iii. art. xi. Ed., 1771. Diss. Inaug. de Syphilide Insontium, &c. Auct. A. Freer. Ed., 1776. Cases in Surgery, &c. By James Hill, Surgeon. Ed., 1772. Observations on Morbid Poisons, &c. By Joseph Adams, M. D. London, 1807, chap. xv. 2d ed.

"In these diseases, the affection of the corion is neither pustular nor tubercular, but consists in inflammation of its substance occurring in many minute points, and causing first an appearance like papulæ, or sometimes only an extensive diffuse redness and roughness of the skin; then desquamation of the cuticle; then pustulo-tubercular or minute hard eminences seldom suppurating completely, but sometimes causing, partly by sloughing, partly by ulceration of the corion, deep foul sores, destroying the corial texture and the bulbs of the hair. This is particularly the case in the Radesyge, the form of disorder prevalent in Iceland, the Scandinavian peninsula, the Feroe Islands, and the peninsula of Jutland. In those prevalent in Italy, Austria and Crim Tartary, ulceration of the corion appears to be less frequent.

"The limits of this treatise do not permit me to enter at large into the history of these diseases, which, perhaps, are not to be viewed as merely cutaneous affections; and I shall simply refer to the best sources for further information.<sup>1</sup>

"To this head also may be referred some of the cutaneous eruptions which occur either among the secondary symptoms of syphilis, or in the persons of those who, for this disease, have been subjected to one or more courses of mercurial medicines. Though these eruptions may appear sometimes in the form of *papulae*, sometimes as a variety of *rupia*, and sometimes as *ecthyma*, they are also not unfrequently of the chronic pustulo-tubercular nature, originally taking place in the corion, and causing more or less ulceration of that membrane. Their connection with inflammation of the mucous and fibromucous membranes is well known.

"Upon elephantiasis so much accurate information has been of late years collected by Dr. Adams, Mr. Lawrence and Dr. Lee, that little difficulty can be experienced in settling its character as a morbid state of the skin. The case described so well by the last of these observers, I had repeated opportunities of seeing; and the appearance of the skin could leave no doubt of the disease affecting the substance of the corion. The exact nature of this affection is perhaps less easily determined. By calling it a tubercular eruption, after the manner of Dr. Bateman, little exact information is communicated. Bichat states, that he has seen the corion manifestly disorganized in elephantiasis,<sup>2</sup> but says nothing of the anatomical characters of this disorganization. Pinel, Beclard and Meckel are equally silent on this subject. In short, though we have good descriptions of the external visible appearances of Arabian leprosy, an accurate description of its anatomical characters is still a desideratum.

"The chronic soft tubercle (*molluscum diuturnum*), is a rare disease; and I have seen only one example of it in the person of a man of 40, in whom these bodies were disseminated over the cutaneous surface of the face and scalp, the trunk, the upper extremities, the nates and thighs. Of two of the larger tumours which were removed from the *palpebræ*, the greater part was composed of firm, tough, whitish-gray matter, of the consistence of condensed cellular texture, penetrated through its whole extent by numerous minute blood-vessels, but exhibiting in no other respect traces of organization. This substance, when macerated in water, was resolved into gelatinous, flocculent filaments, easily lacerable, and presenting no definite structure. Imbedded in this, and removable most easily by maceration, were several small bodies not larger than a pin head, like fat in appearance, of a regularly spheroidal shape, of a lemon-yellow colour, and specifically lighter than water. The matter of these bodies was unctuous. It communicated an oily stain to paper; it liquefied and became transparent at a temperature not exceeding 97° Fahrenheit, so that when attached to the body, it must have been

fluid; it was insoluble in alcohol, ether and water, but formed in the volatile oil of turpentine a colourless solution. When this was exposed to the temperature of the spirit-lamp, the greatest part of the volatile oil was evaporated, leaving a transparent, colourless, but viscid and semifluid substance, communicating to paper a stain becoming less deep, but not wholly removable by exposure to a high temperature. These results favour the idea that the matter of these bodies is oleaginous: but I was unable to observe any action of *aqua potassæ* or *aqua ammoniæ*, after repeated trials, both at the ordinary temperature of the atmosphere and when liquefied by a gentle heat. By the sulphuric acid it is hardened and blackened; by the nitric acid its yellow colour is rendered more intense.<sup>3</sup>

"Whether the presence of these yellow adipocirous bodies is uniform in the *molluscum* I have had no subsequent means of ascertaining. If they are, it may be reasonably conjectured that their formation depends on some morbid or vitiated state of the sebaceous follicles.

"Wart and corn are believed to depend on morbid accumulation of cuticle. The former, however, is vascular at its basis; and it may therefore be inferred that its production depends on morbid action of the surface of the corion at the particular point at which it appears.

"2. *Dermatæmia Dermatorrhagia*.—Hemorrhage of the skin appears under two forms; either that of a bloody or blood-coloured fluid oozing from certain regions, or of blood effused in the form of purple specks, spots, patches, or livid stripes on the surface of the corion below the scarf-skin. The former discharge is rare, and takes place chiefly as a supplementary evacuation to some natural one accidentally suppressed, as the menstrual discharge in females. The latter is of a different nature, and is both the effect and proof of a morbid state of the system.

"Restricted in this manner, hemorrhage from the corion may take place in two modes; either when the corion only is affected, or when it is affected in common with many other membranes. The first case constitutes the simple purple disease (*purpura simplex*) of authors; of the second we have examples in the hemorrhagic purples (*purpura hemorrhagica*) or land-scurvy, and in the genuine sea-scurvy (*scorbutus*.)

"The anatomical characters of the disease consist in bright red or crimson spots, becoming in a day or two purple or livid, afterwards brown, and when about to disappear, assuming a yellow tint. They are occasionally attended with long livid stripes (*vibices*) or patches (*ecthymomata*), and in some instances, the cuticle is raised into vesicles or large purple blebs (*phlyctenæ*), containing bloody or purple serous fluid. These spots consist of blood or bloody fluid, effused on the outer surface of the corion, which is soft or pulpy, velvety, and reddish, from injection of its vessels.

"3. *Angiectasis*.—Anastomotic aneurism is frequent in the corion, and has been observed by J. Bell, Freer, Travers and Wardrop. Though congenital, it must not be confounded with the *navus maternus* or birth-spot (*Penvie*), which appears to consist in a peculiar original malformation of the corion. A similar congenital defect is the white-spot (*leucosis, leucathiopia*), which consists in the absence of the polished vascular surface of the corion. Occasionally it takes place during life, and in minute spots is observed to follow diseases in which the cuticular surface of the corion has been destroyed by ulceration.

"4. *Meliceris*, Cutaneous Wen. The only encysted tumour which takes place in the skin consists in the immoderate enlargement of one or more of its mucous follicles, in consequence of obstruction of the excretory duct. When from any cause this takes place, the sebaceous matter, which in the healthy state is propelled to the surface and removed, accumulates in the interior of the follicle, which is thus inordinately distended, till, by removing the obstruction, the orifice is opened and the inspissated matter eliminated. It almost invariably again accumulates unless care be taken to keep the excretory duct pervious,—an object which is most easily and certainly attained by frequent ablation. This mode of explaining the origin of the cutaneous folliculated tumour was understood by Morgagni,<sup>4</sup> Haller,

"*Scirrhus-carcinoma* of the skin is not uncommon. Though it may occur in any part of the cutaneous covering, it commences most frequently in situations where the corion is delicate and thinly covered. The skin of the face, especially of the eyelids, prolabium and nose, is a frequent seat of this disorder; and next to these, perhaps, are to be placed the nipple of the female and the penis of the male, the corion of which is liable to be affected by this morbid structure. The scrotum is very often the seat of that peculiar carcinomatous destruction occurring in the persons of chimney sweepers. In all these cases the structure is much the same. In the situation of the corion is seen a tough firm substance of fibro-cartilaginous structure, the fibrous bands being generally arranged in a waving direction. In the most distinct example of the disease which I examined personally—a case of scirrhus-carcinomatous degeneration of the whole skin of the penis—these fibrous bands were disposed transversely to the long direction of the part, and appeared to consist of a fibro-cartilaginous long band folded repeatedly on itself.

"The reparation of the corion when destroyed has been maintained by many authors. Notwithstanding their assertions, however, this membrane is never, after its substance has been injured, restored to its original state. The breach is filled up by firm cellular tissue, the upper surface of which never acquires the organization of the outer surface of the corion. It is nevertheless capable of furnishing cuticle by which this new corion is covered. These facts may be verified in the cicatrization of burns and other injuries in which the corion has been destroyed.<sup>4</sup>

"The *nails*, like the cuticle, may be diseased in consequence of a morbid state of the corial surface and vessels by which they are nourished. In one or two instances of strumous children I have seen them fissured into several longitudinal portions, much thickened and indurated like horn, and incurvated. In others of the fingers of the same individuals, they were small and imperfectly developed; and in some their place was supplied by a small portion of thick horny cuticle. Similar changes are sometimes induced by disease or by injury.

"Of the *hairs* the most extraordinary morbid state is the Polish plait (*plica Polonica*); so named from being endemial in Poland, Lithuania, Hungary and Transylvania, from the source of the Vistula to the Carpathian mountains. It occurs also in Prussia, Russia, Switzerland, and in some parts of the Low Countries. It is impossible to doubt that this anormal condition of the hairs depends on disease taking place in their bulbs or nutritious sacs. This is proved by the state of the skin from which the diseased hair grows, and by the unctuous, viscid and blood-coloured fluid which the hairs in this state contain. We nevertheless possess no very precise information on the nature of this diseased state of the capillary bulbs; and in the absence of exact facts I abstain from offering conjectures.

"The piliparous sacs lose their energy under certain morbid states of the system; for instance, fever, pulmonary consumption, and the constitutional symptoms of lues. The hairs then drop out; and if at this time the bulbs be examined, the sacs are found to contain, according to Bichat, at least in persons who have passed through fever, the rudiment of new hairs. The shedding of the hairs, which takes place in the decline of life, and the period of which varies remarkably in different individuals, Bichat represents as depending on a total death of the piliparous sacs.

"Accidental and anormal development of hairs is not uncommon. In the skin this appears in the shape of hairy moles and similar congenital marks.<sup>5</sup> Their occurrence in the stomach, intestines and bladder, as noticed by a variety of authors, is also to be regarded as

anormal. Lastly, the accidental development of hairs is observed in encysted tumours, especially those of the ovaries, in which masses or balls of hair mixed with fat, oleaginous, or adipocirous matter, are not unfrequently found.<sup>6</sup> On the mode in which these hairs are formed nothing satisfactory is known.<sup>77</sup>

The last system of classification is that adopted by Mr. Erasmus Wilson, in his work already referred to. He calls it the *Natural System*, resting upon Anatomy and Physiology. "The dermis and its dependencies, its glands, and its follicles, are the undoubted seat of all the changes which characterize Cutaneous Pathology."

The following is Mr. Wilson's classification arranged in a tabular form.

"I. DISEASES OF THE DERMIS.		
Inflammation . . . . .	Congestive	{ Specific . . . { Rubicula. Scarlatina. Variola. Varicella. Vaccina.
		{ Non-specific . . { Erysipelas. Urticaria. Roseola. Erythema.
	Effusive . . . . .	{ Asthenic . . . { Pemphigus. Rupia.
		{ Silenic . . . { Herpes. Eczema. Sudamina.
	Suppurative . . . . .	{ Impetigo. Ecthyma.
	Depositive . . . . .	{ Strophulus. Lichen. Prurigo.
	Squamous . . . . .	{ Lepra. Psoriasis. Pityriasis.
	From Parasitic Animalcules . . . . .	{ Scabies.
Hypertrophy of the Papillæ . . . . .	{ Ichthyosis. Tylosis. Clavus. Verruca. Carnua.	
Disorders of the Vascular Tissue . . . . .	{ Vascular Nævi. Purpura.	
Disordered Sensibility . . . . .	{ Hyperesthesia. Pruritus.	
Disordered Chromato- genous Function . . . . .	Augmentation of pigment . . . . .	{ Nigritics. Pigmentary Nævi.
	Diminution of pigment . . . . .	{ Albinismus. Vitiligo.
	Alteration of pigment . . . . .	{ Ephelis. Lentigo. Chloasma. Melasma.
	Chemical Coloration . . . . .	{ Oxyde of Silver Stain.
II. DISEASES OF THE SUDORIPAROUS GLANDS.		
Augmentation of Secretion . . . . .	Sudatoria.	
Diminution of Secretion . . . . .	Abnormal Odour, Colour, &c.	
Alteration of Secretion . . . . .		
III. DISEASES OF THE SEBACEOUS GLANDS.		
Augmentation of Secretion . . . . .	Stearrhæa.	
Diminution of Secretion . . . . .		
Alteration of Secretion . . . . .		
Retention of Secretion . . . . .	{ Duct Open . . . . .	{ Ichthyosis Sebacea. Comedones. Sebaceous Accumulations. Small Sebaceous Tumours, (Molluscum Contagiosum.)
		{ Duct Closed . . . . . { Sebaceous Miliary Tubercles. Calcareous Miliary Tubercles. Serous Cysts. Encysted Tumours.
Inflammation of Glands and adjacent Textures . . . . .	{ Acne. Syccosis.	
IV. DISEASES OF THE HAIRS AND HAIR-FOLLICLES.		
Augmented Formation . . . . .	Pilous Nævi.	
Diminished Formation . . . . .	Alopecia.	
Alteration of Colour . . . . .	Canities.	
Disease of the Hair-Pulps . . . . .	Plica Polonica.	
Disease of the Follicles . . . . .	{ Inflammatio Folliculorum. Favus.	
Abnormal Direction . . . . .	{ Trichiasis. Felling. <sup>77</sup>	

It will be seen, from the preceding systems, that the views of dermatologists tend to an arrangement of diseases of the skin, based upon an anatomical and physiological basis, which, although as yet confessedly imperfect, is preferable to any arrangement deduced from the more external features or physiognomy of the cutaneous eruption and other disfiguration, as adopted by Plenck, Willan and Bateman,

<sup>5</sup> *Haller. Elementa Phys.*

and, with more qualification, by M. Rayer himself. Plumbe, while he admits the value of the anatomy and physiology of the skin as a guide, lays stress on the etiology of the diseases of this tegument, in connection, especially, with constitutional conditions of the system, which originate or modify them. Even if we should fail to establish a successful classification from these premises, it is all important that we should continually bear them in mind, in proceeding to the treatment of cutaneous diseases; for in this way alone shall we be saved from the empiricism which, up to the present day, is still prevalent when this subject is brought up. Plumbe's criticism, as conveyed in the following words, is too well founded:—"A classification of the external and ever-changing forms of the accumulated secretion of disease on the surface—one day a pimple, the next a vesicle, on the third a scab or crust, the fourth a falling scale, the fifth a red spot! This might have served the purpose at the time, for want of a better; but to pronounce it a better classification than one founded, whether with solid foundation or not, by its originators, on etiology, or the causes, external and internal, of the cutaneous disease, would be manifestly absurd." And again:—"Purpura or scurvy stands foremost among these. Its different states, in different and not unfrequently in the same person, may, at uncertain periods, be found putting on the mask of pimple, vesicle, pustule, scab, or scale; blue flat discolorations; large vesicles, half filled with bloody serum, and others, smaller in dimensions, of a yellow, transparent colour. Again, it may show itself in the form of what is commonly called thrush, either in the infant or adult. It may appear in the form of *erythema nodorum*, which is a scorbutic inflammation of the integuments, ending in a partial effusion of serum and blood into the cellular structure. *Erythema andrupia* are the pustular forms of it, ending in scabs." [P. 44, op. cit. Am. Ed.] But, whatever differences may exist between the modified artificial arrangement of M. Rayer, and the alleged natural one of Mr. Wilson, or between them and the mixed one of Mr. Plumbe, there is among these writers a general agreement respecting the organic condition of the skin, in most of the forms of eruption which we commonly speak of as constituting its diseases. Inflammation is the primary and chief pathological change, that on which the phenomena that more immediately strike the eye depend. According to the division of the cutaneous system affected, and in degree to the duration of the affection, will be the physiognomy of skin diseases. M. Rayer, in his table, (p. 21,) includes the larger number of diseases of the skin, under the head of "inflammatory affections distributed according to the number and form of their elementary lesions;" and of these, the larger number, or nine classes, have only a single elementary form. "Peculiar states of the skin, not referable to inflammation, are comparatively few." He enumerates some, again, as "morbid states of the secreting function," and, under another head, introduces "neuroses of the skin." His fifth chapter is "faulty structure or unusual states of one or other of the elements of the skin;" and the sixth is "degenerations." In a second division, he places "alterations of the dependencies of the skin," such as diseases of the sebaceous and piliferous follicles.

Recurring to the original proposition, we find a vast majority of cutaneous diseases, viz., *exanthemata*, *bullæ*, *vesiculæ*, *pustulæ*, *furunculi*, *gangrenæ*, *papulæ*, *squamæ* and *tubercula*, recognized as depending on inflammation of a single elementary form, and *syphilis*, *ambustio* and *pernio*, having several elementary forms inflamed.

Mr. Wilson, also, while he refers the larger number of cutaneous diseases to the dermis, regards the organic changes constituting them as depending on inflammation, in its several varieties of *congestive*, *effusive*, *suppurative*, *depurative*, *squamous*, or from *parasitic animalcules*.

Mr. Plumbe, although he does not lay down thus broadly inflammation as the sole pathological basis of diseases of the skin, is hardly less explicit, when introducing their several divisions to his readers; as when he speaks of some of these diseases being marked by chronic inflammation of the vessels secreting the cuticle, others characterized by active inflammation, with or without constitutional debility or derangement of any kind.

The general division of diseases of the skin into those of an acute and febrile, and those of a chronic and apyretic character, is generally admitted; but we much fear that too broad a contrast is supposed

to exist between the two, to the oblivion, if not actual denial, of the chronic class being also inflammatory, and of their having, like the acute, their periods of incubation, attack and decline. Few of the diseases of the skin, if carefully watched from their early inception, would be found wanting in these stages; and the chief difference between the two divisions will, on careful analysis, be found to consist in this, that the acute and febrile, after having run a definite course, terminate either in health or death—putting aside, for the moment, complications which do not essentially belong to them; while the slow, or chronic, go through a similar course, but with a termination only temporary and incomplete; so that, after a period, the cutaneous irritation and congestion, or other organic changes are renewed, either in the same or at another region, and go through a series of stages like the first. It is this partial suspension and renewal, more or less complete, according to the hygienic system pursued by the patient, that give reputation, for a season, to a particular remedy or plan of treatment, and tantalizes the sufferer with the prospect of a cure, which, in a short time, is shown to be fallacious. Until we get the measure of these alternations of relief and exasperation, and of the constitutional state and changes accompanying them, we cannot promise ourselves to make any great advances in the rational therapeutics of cutaneous diseases.

In the acute febrile diseases of the skin, and particularly in the exanthemata, or eruptive fevers proper, the mucous membranes suffer often as much as the dermoid texture. Their being primarily affected, has been already adverted to. In the case of the skin, however, the inflammation is generally diffuse, and extends over the entire surface; whereas the mucous membranes are but partially affected, or, at any rate, suffer most in particular regions, as the fauces in scarlatina and small-pox, the air-passages in measles, &c., at any rate, at the beginning or first stage of the disease; while, towards its decline, the lower bowels may become the seat of secondary irritation, or phlogosis, manifested by diarrhoea, or the kidneys be the organs thus secondarily affected, giving rise to albuminaria and anasarca. He who does not continually carry in his mind this connection in function as well as in disease, between the two great divisions of the general tegumentary system, will have very limited views of the pathology of febrile cutaneous diseases, and be not a little embarrassed in arriving at a rational treatment.

In a more advanced part of the present volume, the reader will find a "parallel between the diseases of the skin and those of the mucous membranes," which might have been introduced with advantage, by the author, at a much earlier period. "If we except," says M. Rayer, par 1282, "the white wheals of urticaria and the patches of roseola, we find in the mucous membranes almost the whole of the varieties in form and appearance, presented by the exanthematous inflammations of the skin." "As to the brown, gray, or slate-like discolorations presented by the mucous membranes, in consequence of their inflammation, we observe very similar tints following chronic inflammatory affections of the skin." M. Rayer then proceeds to describe the various forms of eruption on mucous membranes, such as exanthemata, bullæ, vesiculæ, &c., similar to those seen on the skin. Mr. Wilson very properly places rubeola, scarlatina, variola, varicella, vaccinia, under the head of inflammation of the dermis and mucous membranes, with constitutional symptoms of a specific kind. It is now eighteen years since the editor, in his "Syllabus of a Course of Lectures on the Institutes of Medicine and Medical Jurisprudence," printed for the use of his class, (at the Philadelphia Medical Institute) enumerated variola, varicella, rubeola, scarlatina, erysipelas, urticaria, and herpes, as a class designated as "Diseases affecting the cutaneous and mucous systems simultaneously, or cutaneo-mucous diseases." To this conclusion he was the more determinately led by the results of extensive clinical experience in epidemic small-pox, measles and scarlatina.

It is not meant that the treatment of the exanthemata should be described here, in anticipation of the time when it will come up in regular order. One remark, however, of practical importance may be made, viz., that independently of the varieties in their intensity and progress, depending on differences in individual constitution, we meet with great modifications during different epidemic seasons, requiring corresponding changes in treatment; so that scarlatina, for instance,

which in one year will be simple and benign, in another displays greater malignity; and that which, at one time, will be benefited by the use of lancet and free purging, at another will not allow of evacuations of this nature, but, on the contrary, demands early recourse to stimulants.

In the treatment of the chronic affections of the skin, we are yet without systematic therapeutics; but, on the contrary, learned empiricism has too much sway. The chief indications to be fulfilled are, the removal of local excitement, and often inflammation, and a restoration of healthy secretory function. The morbid action, undue determination and secretion, being arrested, there is seldom much difficulty in procuring a ready absorption of the new and abnormal deposits on the dermoid tissue, or between its laminae. In carrying out the above indications, we shall be not a little aided by recurrence to the principles already laid down, respecting the general sameness of dermoid and mucous membranes, (see also Mandl, *Man. d'Anat. Gen.*, p. 537,) and of the sympathy, as well as antagonism of action between these two portions of the tegumentary system, and also as an extension of this principle, the dependence of the cutaneous or local malady on the constitution. In fact, the principles and practice that govern the treatment of a chronic inflammation of a viscus, ought to direct us in that of a cutaneous disease. The dermoid system, says Mandl (*op. cit.* p. 547), may be regarded as an extended gland, secreting solid matters, viz., the epidermis and the epithelium. Hence, while we abate the afflux by purgatives and diuretics, we soothe irritation by baths of various kinds, and at such a temperature as the experience of the patient and the powers of reaction may justify. After perseverance, for a period, in this course, we direct some one, or a succession, it may be, of those medicinal substances which are believed to display alterative properties. These are referrible to two great classes: the abaters of action, or contra-stimulants proper, and those which tend to remove, by absorption, and renovate the tissues. Among the former, the antimonial preparations, represented by tartar emetic, are entitled to a precedence, and next among the mercurials, calomel and blue mass. The latter display very decided powers of reducing morbid excitement of the membranes; and on this account, as well as by their beneficial action on the mucous membranes and digestive apparatus generally, they are entitled to rank high, in the list of curative agents, in protracted chronic affections of the skin depending on inflammation. Mercurials may well be alternated with tartar emetic, by their being given in small doses, and aided by large use of diluents, so that neither the stomach nor bowels shall be harassed or disturbed nor pyalism be induced. The warm or vapour-bath, regularly employed, is an extremely useful adjuvant to the medicines just mentioned.

Without foregoing the use of antimonials and mercurials, even where they have not answered expectation, recourse might be had to salines; either those of a purgative or a diuretic nature, and particularly the latter. Various mineral waters answer a good purpose in this way, after having, it is presumable, entered largely into the circulation and penetrated into the dermoid tissue. Still contributing to the end proposed, of abating cutaneous excitement and modifying morbid secretion of the skin, will be the administration of colchicum and digitalis. The first of these can be usefully combined with salines or alkalies, or magnesia, according to the state of the primæ viæ, and the propriety of acting on the bowels or of modifying the renal secretion.

Narcotics,—hyoscyamus, belladonna, stramonium, dulcamara, and conium—are also coincident with the measures just proposed; and they may be combined with mercurials or the tartar emetic, or given alone. They not only allay irritation of the skin, but abate, by their effect on the nervous system, the process of morbid nutrition and deposit. It is not desirable to give any of them in a dose beyond that which produces some sensible effect as evidence of the purity of the article. More is gained by their regular use for a length of time than by the administration of large doses, whose operation may be too manifestly narcotic. The alternate or even combined use of this class of medicines with alkalies, is often decidedly efficacious in numerous cutaneous diseases, in which there prevails either irritation of the skin itself, or of the digestive mucous surfaces, or of the renal apparatus.

The external medication in harmony with the internal, as just recommended, will consist in the employment of the warm, or tepid, or simple vapour bath, warm fomentations or emollient cataplasms, and infusions of some narcotics, or ointments of the latter. Preparations of lead, and more particularly of the subacetate adequately diluted, will, in some cases in which the disease is of circumscribed extent, exert a sedative effect. Recourse to articles of this nature ought, however, always to follow the general or constitutional treatment, and to be used with great circumspection, if at all, in those forms of disease which assume an ulcerous character, and have been long discharging, and which we may encounter in children during dentition, or in aged persons.

When, on the other hand, either from the duration of the disease, and the subsidence of irritation and excitement, and the absence of disorder of the digestive mucous surfaces, or the want of success from the soothing treatment, more stimulating remedies are demanded, we shall have recourse to sulphur, iodine, arsenic, cantharides, and the different mineral and vegetable tonics and astringents.

Sulphur has long enjoyed a great reputation for the cure of some of the most common, and at the same time occasionally inveterate diseases, such as scabies, or itch and lepra. But, if had recourse to early, when there is yet much irritation and vascular excitement, or if it fail to purge, this medicine will not only disappoint us of the desired effect, but prove positively injurious. Hence, it is most efficacious when combined with salines in either natural or factitious mineral waters, or, as in the popular formula, with cream of tartar, and occasionally with magnesia. Used in this manner, the sulphur practice is a transition from the reducing or sedative to the stimulating plan of cure; and may be well entitled to a trial before medicines of more power, either for good or evil, are resorted to. In lymphatic temperaments, and in broken-down constitutions, suffering from scrofulous eruptions, sulphur may be given at the same time with some preparation of iron, or, if the indications be more direct, with a vegetable bitter. In venereal eruptions it will be administered in conjunction with mercury.

Iodine preparations are contra-indicated in those cases in which there is either much vascular or nervous excitement, or in which gastro-enteric irritation prevails. The least stimulating form is the iodide of potassium; the most so, the alcoholic tincture of the iodine itself. Between these two are the compound solution and compound tincture of iodine. Largely diluted in a solution of some purgative salt, the iodide of potassium may be administered after the subsidence of the first stage, that of gastro-intestinal and febrile irritation, of various cutaneous diseases, and more especially the papular and tubercular forms. In this state of combination, or even alone largely diluted, the iodide can be continued for a length of time, until every tissue is permeated, and in a degree, its organic nutrition modified. It often comes in opportunely to relieve the depression of the system and feeling of wretchedness induced by the uncalled for, or excessive use of mercury, and realizes that which was expected from the latter.

No benefit can be promised from the tincture of iodine that is not procurable with less inconvenience and drawback from the iodide of potassium, or if a more stimulating preparation than this latter be desired, we have the solution of the ioduretted iodide of potassium, or the compound solution of iodide of potassium. The use of this medicine will be alternated with that of compound saline waters and sometimes in conjunction with them, and some one or other of the narcotics, where the irritation of the skin, even in the chronic stage of the disease, is still considerable. Its use is compatible with abundant nutriment, should this be deemed advisable, and especially so in anæmic subjects, and also in those of a lymphatic temperament.

Arsenical preparations used in the appropriate period of a cutaneous disease, that is, when the stage of inflammatory and irritative excitement has subsided and when there is no complication of gastro-enteritis, have often a singularly good effect. They are particularly adapted to the squamous or sealy affections of the skin. The dose should be small, and, if symptoms of irritation are induced by the medicine, conium or some other narcotic should be associated with it. The safest formula for the administration of arsenic is the solution of the arsenite of potassa, or Fowler's solution, as it is more generally

called. Of late, the solution of the iodide of arsenic and mercury, or Donovan's solution has been given with great success in obstinate cases of long standing, particularly those of syphilitic eruption and of lupus.

Arsenic requires more care in its administration in sanguineo-nervous habits, and in these the customary cautions respecting its use should be promptly enforced. When the patient feels any febrile movement, heat, thirst and a feeling of weight and heat at the epigastrium, or complains of heaviness and pricking sensation about the eyelids followed by puffiness of these parts, the use of the medicine should be suspended, and in its place mild aperients prescribed. The resumption of the arsenical preparation must be in a smaller dose than that in which it was first administered.

Cantharides is a remedy of great power in certain chronic skin diseases, as eczema, lepra and psoriasis; but its exhibition requires caution, and it should not be continued after any symptoms of urinary irritation are manifested.

There are two stages of chronic cutaneous diseases in which the state of the constitution requires careful notice, and the use of active general remedies, but of opposite characters. Of the first, or that of excitement, I have already spoken, as well as of the depleting and sedative remedies required for its removal. In the second, or that of debility and imperfect nutrition, owing to chronic derangement of the digestive organs, a tonic course is indicated. This may be either the primary one, or adjuvant to the special treatment; as when we administer iron, in addition to, or in combination with, sulphur or iodine; quinine with mercury. In all cases of complication of constitutional disorder with chronic cutaneous affections, it will be wiser to make the removal of the former the chief object, and to direct the remedies for the latter in this subordination. The iodide of iron, in the form of solution, as directed to be prepared in the Pharmacopœia of the United States, is adapted to a large number of cutaneous diseases of a chronic character, occurring in cachectic habits or in constitutions that have long suffered from disorder of the digestive apparatus. Auxiliary to its tonico-alterative effects, are the vegetable bitters and certain depurative syrups, such as the compound syrup of sarsaparilla, syrup of pipsissewa, &c.

In anemic constitutions, and particularly in female subjects, suffering from chronic cutaneous diseases, the prolonged use of a chalybeate, combined or in alternation with a laxative, will be productive of much good; as will the sulphate of quinia in those who have been afflicted with periodical fever in its various forms.

In the external or local treatment, of a stimulating kind, great importance has always been attached to baths, in which various substances of an active nature have been held in solution. In aid of internal remedies these will often do much good. Trusted to alone, they will more generally fail us. This class includes the simple and the medicated warm and hot baths. The most conspicuous of the latter are those largely impregnated with sulphur, iodine, corrosive sublimate (bichloride of mercury) the alkalies and mineral acids; the two former are combined either with water or with vapour.

Preparatory to the systematic and prolonged employment of stimulating baths, it will be proper to subject the patient for some time to the use of the simple warm water or vapour bath; both as a means of removing any remaining excitement of the cutaneous system, and as an aid to diagnosis, by revealing more completely the physiognomy of the disease. The real state of the dermis may be masked by the white branny scales covering its diseased regions, as in the squamæ, or by dry scabs, as in *favus* and *impetigo*. These removed, we often find active dermoid inflammation, requiring a soothing and sedative treatment in place of stimulating applications, that seemed to be indicated by superficial signs of an indolent state of the parts. Plumbe (p. 41) points out the difficulty of diagnosis in many cases of scalled head of pauper females, in which he had to deal with masses of scabs, and scales interwoven and matted with the hair of these parts, requiring for their removal ointment, the use of soap and warm water, before an opportunity was offered of examining the diseased cutis. In all chronic affections of the skin, a sponge dipped in warm water should be rubbed over a part, at least, of the diseased surface, and the slightly adherent cuticle removed, so as to allow of the real state of the dermoid tissue being seen.

Of the stimulating baths, those of the sulphurous kind have been the

most extensively used, and productive of the greatest good in a large number of diseases of the skin. Their beneficial operation depends mainly on their temperature and duration, as already indicated by M. Rayer, parag. 127. Little can be expected from a sulphur bath, unless it be at least 90° F.; but in chronic disease and in apyretic states of the system, it may be brought nearly to blood heat. When the patient is required to spend a long time in the bath, and from one to three or four hours is not an uncommon period, the temperature should be such as just to convey a grateful sensation of warmth, and no more. By this protracted immersion time is allowed both for the passage of the simple fluid and its medicated constituent, through the epidermis to the dermis, and for the textural and vital modifications of this latter requisite for the removal of the disease. It needs little reasoning to show, that the period in which the external treatment by bathing is carried on, is that in which alteratives of various kinds may be resorted to; and, if they do not exert a principal effect in procuring a favourable result by their action on the capillaries, saline and sulphurous mineral waters, natural or factitious, blue mass, or iodide of potassium, according as there is any constitutional excitement or syphilitic or scrofulous taint, will be found to meet the indications at this time.

Experience has not yet enabled us to define the cases in which the water-sulphurous bath should be preferred in the dry vapour or sulphurous fumigation. In a general way, the latter may be said to be best adapted to old forms of cutaneous disease, in habits in which there are a languid circulation and general debility. It is true that patients often complain of exhaustion after these fumigations; but the debility is here obviously of the indirect kind, following increased activity of the circulatory and respiratory functions.

The alkaline sulphurets, as those of potassa and soda, or rather of potassium and of sodium, are employed in the composition of artificial baths—in various proportions and combined with other matters. One of the formula, recommended by M. Rayer, consists in dissolving 3iv of sulphuret of potassium in thirty gallons of water. It must be prepared in a wooden bathing vessel. Dupuytren's gelatino-sulphurous bath is prepared by adding one pound of Flanders glue (previously dissolved in water) to the sulphuretted bath just described. This is an imitation of the Barèges waters, so celebrated in France for the cure of obstinate diseases of the skin; although recent analysis (by M. Longchamp) shows that sulphuret of sodium is the predominant compound into which sulphur enters in these waters. Their temperature, in the different springs, is from 85° F. to 114° F. Of 111 military men affected with various forms of psoriasis and impetigo, vaguely called herpetic disorders, who visited Barèges in 1829, 66 were cured. The cures of the more simple kinds, 51 in number, were 31. The proper imitation of the Barèges water for bathing is as follows: crystallized sulphuret of sodium, carbonate of soda (crystallized), chloride of sodium of each 64 grammes; pure water 320 grammes. These salts are to be dissolved in the water, and the solution is to be promptly poured into a bottle closely corked. This quantity will serve for a common bath of about twenty gallons.

Baths of water impregnated with iodine, or the iodide of potassium, in different degrees of strength, have been spoken of by M. Rayer and the formulæ, after M. Lugol, for their preparation will be found in the "formulary" at the end of this volume. Iodine may be readily vapourized in water of a moderate heat, and in this way applied to the cutaneous surface for the required period.

Washes made of a solution of corrosive sublimate, are more used than a general bath of this salt. The solution of the bichloride of mercury of the London Pharmacopœia is made of ten grains of the mercurial salt and the same quantity of hydrochlorate of ammonia, dissolved in a pint of water. Diluted with an equal quantity of water, this solution is used as a wash for herpetic and scabious eruptions. In smaller proportion, or half a grain to a pint of water, Baume recommended the solution in the form of a pediluvium, to produce salivation. He directed the feet to be immersed in it for a period of two hours. Such a practice will be found for the most part inert, as this salt of mercury, externally applied, is little liable to salivate unless the cuticle be removed or abraded.

Alkaline baths have been occasionally used with advantage in some chronic cutaneous diseases; but whether as simple exciters

of the skin, or acting on it chemically, we are not apprised (see parag. 131).

Still more decided benefits may be expected from baths, to which some one of the mineral acids, and particularly the nitric, and nitromuriatic or nitro-hydrochloric acid, has been added, in the proportion of 6 to 8 fluid ounces of the latter to 30 gallons water, in a wooden tub. Where we are prevented from directing the internal administration of the mineral acids, of which M. Rayer thinks so highly, (parag. 165,) recourse should be had to their employment externally under the same conditions as those that govern them in the former case.

Belonging to the class of stimulating baths, are those of sea-water, brought up to the degree of blood heat, or a little below, as at 96° F. In torpid habits the temperature of the bath may extend beyond 100° F.

If the situation and circumstances of the patient do not allow of recourse to medicated baths, a good substitute will be found in applying the active articles, such as sulphur and iodine, and even the mineral acids, in the form of ointment. Iodine, in this way, has been found to be one of the best remedies, especially when conjoined with its administration externally, in *prurigo senilis*. To give full efficacy, however, to this form of medication, a simple water or vapour bath should be employed daily, or on alternate days, so as to place the skin in the most favourable state for absorption, and to remove partially detached epidermis and adherent morbid secretions. If the disease embrace an extended cutaneous surface, it will be better to rub in carefully the ointment prescribed for the occasion, on a limited region at one time, and then apply it in like manner to another, than to attempt to anoint the entire surface, and most probably fail thereby in doing justice to any one portion.

To the class of external stimulating applications belong, in an eminent degree, those of a caustic or escharotic character, such as chlorine, nitrate of silver in substance, corrosive sublimate in strong solution, tincture of iodine, iodide of mercury, chloride of antimony, sub-acetate of copper, &c., and of a somewhat milder nature solutions of the chlorides of soda and lime, and, with a different view, again, cantharides. I shall not pretend to specify the distinctive merits of these substances, if at any time such an attempt could be successful, but content myself with mentioning that in the milder forms of herpetic eruptions, I have found washes of the chloride of soda or of lime answer a good purpose; and, in the more obstinate diseases, I give the preference to the nitrate of silver. In a bad case of favus (*fungus favosa*) of several years' duration, in which the greater part of the hairy scalp was implicated, I succeeded in entirely removing the disease, by having the head kept shaved and applying a strong ointment of nitrate of silver; administering, however, at the same time, laxatives and iodide of potassium in small doses.

Of all the modes of treatment of chronic diseases of the skin, there is none comparable, for successful and permanent results, to the hygienic; nor can we place any reliance on the most approved therapeutical remedies, unless the rules of hygiene be implicitly followed. All careful observers of the affections of the skin, must be sensible of this truth, which it is difficult, however, to impress fully on the minds of the patients themselves. Impatient to be relieved of a troublesome disease, they fly from doctor to doctor, trying every remedy in quick succession, sometimes at the peril of their lives; but refusing, often, to abide by the dietetic conditions on which alone their cure mainly depends. M. Rayer has pointed out (parag. 113–117) the good effects procurable from an appropriate diet, and, in some cases, from fasting, and the mischief ensuing on errors in regimen. I was early impressed with the facts mentioned by Alibert, (*Precis. Théorique et Pratique sur les Maladies de la Peau*), of a milk and vegetable diet bringing about the cure of some of the most protracted diseases of the skin, which had been rebellious to all other modes of treatment.

But it is not enough for patients to take proper food; they must also enjoy the advantages of adequate exercise and breathe a pure air, at the same time, also, that justice is done to the skin itself, by avoidance of the extremes of temperature, and by recourse, at short intervals, to the use of the bath. Alibert states his having had fre-

quent occasion to observe that, at the hospital of St. Louis, herpetic eruptions, of various kinds, were kept up by defective nutriment and an impure air. In view of the whole subject, the habitual frame of mind must not be overlooked, nor pains omitted to give it a healthy tone.

Coming, also, under the head of hygiene, is change of climate, which in some cases develops, while in others it cures certain cutaneous affections.

The question, to what extent the physician is justified in curing chronic affections of the skin, in reference to any danger of more serious internal disease occurring afterwards, does not admit of a decided answer. All the circumstances of the case must be taken into consideration; the time when the eruption first appeared, whether it followed immediately on some visceral disease; its duration; the general health of the patient at the time; his inherent or acquired tendencies to particular diseases. In those predisposed to phthisis pulmonalis, or to cerebral disease, epilepsy or mania, for example, we should attempt, with great diffidence, any means of suddenly removing the cutaneous eruption; or, if this is done, it ought not to be by external remedies, but rather, mainly, by internal treatment and the use of counter-irritants, or the substitution, for awhile, of a drain by a small blister, or tartar emetic, &c. In children, and in aged persons, the greatest reserve must be exercised in the use of any repellents to the skin, by which either chronic eruptions may be driven away, or chronic sores dried up.

## SECTION I.

### INFLAMMATIONS HAVING A SINGLE ELEMENTARY FORM.

#### I. EXANTHEMATA.

##### Vocabulary, Art. *Exanthema*. *Exanthematous*.

209. I have designated by the title of *exanthemata* several inflammatory diseases of the skin which are characterized externally, at their *acme* or highest degree of development, by the morbid accumulation of blood in a point, a district, or the entire surface of the integuments. These inflammations terminate in resolution, in delitescence or recession, and in desquamation.

This group comprises erythema, erysipelas, rubeola, scarlatina, roseola, urticaria, and several inflammations artificially produced.

210. The common and generic anatomical character of these inflammations is the *red tint* in the parts of the skin affected; the red colour disappears on pressure, and returns immediately on its removal. The injection of the skin, which is slight in roseola and rubeola, and often very passing in urticaria, is more intense and permanent in erythema and erysipelas. Its principal seat is in the vascular network of the skin; but in erysipelas, urticaria, and even in rubeola and scarlatina, it will sometimes extend to the subcutaneous cellular tissue.

The degrees of heat and tumefaction attending the exanthemata are very various. The same thing may be said of the pain, which is sometimes not complained of in roseola, but is often tense and continuous in erysipelas.

When these diseases terminate in resolution the epidermis is detached in scales, as in scarlatina and erysipelas, and in almost imperceptible furfuræ in rubeola and roseola. The greater the injection of the skin has been, the more considerable is the subsequent desquamation; and the thicker the epidermis is, as on the hands, the elbows, and soles of the feet, the more apparent is the process. After the detachment of the epidermis, the skin is smooth and shining, and often redder than in the natural state. After one desquamation in the exanthemata, particularly in scarlatina, a second is often observed to

occur. It would appear in this case that some remains of inflammation keep up the epidermic secretion in excess; in fact, it is only after the skin has lost the morbid redness it had acquired, that the new epidermis puts on the appearance of that which covers the healthy integuments. During convalescence from and at the crisis of several acute diseases, the epidermis is detached from the skin without its having been sensibly inflamed.

211. When death happens on the invasion or during the height of an exanthematous inflammation, if the body be examined a few hours afterwards, scarcely can a few injected capillaries be detected on the surface of the parts that were inflamed. The swelling of the cellular tissue also, is always much less than during life. If the body be inspected several days after death, the epidermis may be detached more readily than from skin unaffected by disease. The epidermis in a general way is found to come from off the sacral region and the trochanters more easily than from any other part, for no other cause apparently than the previous irritation the skin has undergone from the recumbent posture of the patients during their lives.

212. The cutaneous exanthemata coincide with inflammations of the same nature of the gastro-pulmonary mucous membrane. Many of them, indeed, only possess interest in a practical point of view, by reason of these important relations. Among the precursory phenomena which often usher in an attack of exanthematous inflammation, there are some, such as shivering fits followed by moist warmth of skin and frequency of pulse, which are rather expressive of disturbance of the functions generally than of a local affection; others, again, such as redness of the edges and point of the tongue, a greater or less degree of thirst, distaste for animal food, difficulty of deglutition, cough and bronchial rattle, &c., are evidently indicative of an association of some degree of inflammation of the internal mucous membranes with that of the skin.<sup>1</sup> There is sometimes a pretty exact relation between the intensity of the inflammation of the skin and that of these membranes; more frequently, on the contrary, the external evolution of the exanthemata is interrupted by the occurrence in any degree of intensity of such gastro-intestinal, pulmonary, or cerebral affections. It may sometimes happen, too, that other lesions are associated with these already complicated circumstances, which are rendered additionally dangerous according to the importance of the organs implicated and the nature of the cause that produces the additional derangement in the functions.

213. Exanthematous inflammations are generally acute and continued in their progress, and do not often last more than from two to three weeks. Several of them, however, do occur with the intermittent type. These are, indeed, the only class of inflammations of the skin which seem capable of coming on in paroxysms and of presenting true intermissions. When not consequent on a distinct febrile attack, these intermittent phlegmasiæ of the skin most commonly appear during the exacerbations of some affection of the digestive organs, a condition the influence of which is particularly remarkable in the production of urticaria and intermittent erysipelas.

214. In the exanthemata, the limits of the dermis and vascular rete are much more easily demonstrated than on the healthy skin; a simple incision through the substance of the skin is enough to exhibit these two layers; it is then, in truth, as M. Gendrin well observes, if at any time, that we must be induced to conclude that the vascular reticulation and the dermis form two distinct and superposed membranes. When the inflammation has run high, the vascular rete is of a red, and even of a brownish colour, as in erythema nodosum, rubeola, nigra, and gangrenous erysipelas; a certain quantity of blood then appears to be extravasated into the tissue of the skin. Lastly, there sometimes exists an infiltration of serum into the cells of the dermis, a circumstance that frequently happens in erysipelas and scarlatina.

215. The exanthemata at their acme cannot be confounded with any other order of the inflammatory affections of the integuments. When we have to distinguish between the species that compose this group, and to detect them at the bedside of the patient, we must not forget that three other affections implicating the skin may also present themselves under the form of exanthemata, namely, *exanthematous* burn, frost-bite, and syphilis. Among negroes, the red tint of the

exanthemata is of course obscure, and their diagnosis, therefore, more difficult than among whites.

The red colour produced by effusions of blood into the subcutaneous cellular tissue or into the substance of the skin itself, differs from that of the exanthemata in this, that it cannot be made to disappear by pressure. This circumstance, as well as other considerations derivable from the nature of the diseases, should have kept Willan from placing petechial affections and purpura hemorrhagica among the exanthemata. In papular and squamous inflammations, after the detachment or removal of the epidermis, and in vesicular bullous and pustular inflammation after the fall of the scabs, red blotches are perceived upon the surface of the body which are easily distinguished from the primary efflorescence of the exanthemata, by their form and their standing, by the history of the changes the skin had undergone before the appearance of these spots, or better still, by leaving them to themselves for a few days, and giving them an opportunity to put on their essential characters. (a)

(a) The progressive changes on the skin, in the exanthemata, are well described by M. E. Wilson, (*op. cit.*) as follows.

"The immediate seat of the inflammatory congestion of the exanthemata is the vascular rete of the dermis, and the difference of tint observable in these diseases at their height and during their decline, is sufficiently explained by reference to the structure and normal phenomena of the skin. When the degree of excitation of the cutaneous nerves is small, and the arterial determination but little exalted above the ordinary standard, the vascular rete of the dermis is only partially congested, and the redness produced by this congestion is slight; such is the redness, with slight modifications depending on degrees of intensity of nervous excitement, which is seen in erysipelas, roseola, and erythema. When, however, the nervous activity is aroused to its highest pitch of energy, as in scarlatina, the congestion is most intense, and the bright scarlet of the arterial blood coursing through its vessels is little obscured by the thin veil of epidermis which binds it in its sphere. The congestion in rubeola, scarlatina, and variola, is not confined to the parallel strata of the vascular rete of the dermis, as in the second group of exanthemata, but many of the papillæ of the dermis are also distended with blood, and give rise to that punctiform appearance of the redness which is characteristic of these eruptions.

"The crescentic form of the congested patches seen in rubeola, depends upon some unexplained peculiarity in the distribution of the cutaneous nerves, and corresponds with that natural appearance of the skin which is so frequently seen in healthy children, and which is denominated mottled. Again, I have observed, that in injecting the limb of an infant with size and vermilion, I can imitate all the forms of redness seen in the exanthematous diseases, by ceasing to inject from time to time, or by filling the capillaries to their utmost.

"The decline of congestion of the dermis is accompanied by certain alterations in the tint of redness which betokens its presence. Thus the red patches are observed to lose their vivid brightness, to become duller in their hue, and to pass through various shades of purple, until they become bluish and livid. These changes depend upon the degree of excitement of the cutaneous nerves at the several periods indicated by alteration in the colour of the exanthem. When the nervous energy is at its highest point, the capillaries contract actively upon their contents, and maintain a rapid current of arterial blood through their channels. But as the nervous excitement becomes gradually allayed, the capillaries lose their power to contract, and become distended by the full stream that moves more and more tardily onwards in its course, giving time to the arterial current to combine with the carbon of the tissues through which it flows, and become converted into venous blood.

"The above phenomena will explain, also, the differences of colour which the exanthem may assume at an earlier period than its decline, and even from the commencement of its appearance, as, for instance, in scarlatina maligna, or more strikingly, in rubeola nigra. The first step or motive influence by which this change is effected, is depression of nervous power; this depression, depriving the capillaries of their tonic power, or, in other words, of their means of resisting the pressure of the arterial current, they yield, they become dilated, and from

<sup>1</sup> Talma. Diss. sur les maladies éruptives, in-4. Paris, 1819, No. 25.

216. The exanthemata sometimes complicate other inflammatory affections of the skin, and in particular those of a papular, vesicular and bullous kind. Severe erysipelas, left to itself, is often accompanied by bullæ similar to those of pemphigus; viewed in this way it seems to form the intermediate link between the exanthematous and bullous forms of inflammation.

The determination of the other affections that may be associated with the exanthemata is one of the most interesting points in diagnosis: and it is always of importance to establish distinctions between these complicated instances and the more simple cases before laying down rules of treatment.

#### ERYTHEMA.

Vocab. Art. *Erythema*, *Efflorescence*, *Red-gum*, *Intertrigo*, *Maculæ volatiles*.

217. Erythema is an uninfected exanthema occurring without fever, characterized by one or more red blotches, varying from a few lines to many inches in diameter, confined to one or scattered over several regions of the body, the duration of which, in the acute state, varies from one to two weeks.

218. Acute erythema presents seven principal varieties: 1st. *Erythema intertrigo*. In new-born babes and persons who are somewhat corpulent, the repeated rubbing of two contiguous surfaces sometimes gives rise to this variety, which may occur under the mammæ, in the axilla, the groins, the upper part of the thighs, the navel, between the buttocks, and, generally, wherever the skin lies in folds, or is wrinkled. Intertrigo may also be occasioned by the contact of the

capillaries, which they were, they are converted into a venous plexus, through which the blood moves feebly and slowly, gathering carbon in its tardy course.

"Congestion of the capillary rete of the dermis necessarily gives rise to tumefaction, the extent of swelling being, to a certain degree, the measure of the increased quantity of blood distributed through the part. Hence it is obvious that all exanthematous patches must be raised above the level of the surrounding skin, even although the degree of tumefaction be really very slight.

"Another cause of tumefaction in an inflamed and congested tissue, also follows as a natural consequence from the over-distension of its vessels. I have already endeavoured to show that the nervous excitation of the part must have diminished before over-distension of the capillary vessels can take place, but so soon as that change has ensued, another phenomenon is immediately developed. This is transudation of the watery part of the blood by imbibition into the surrounding textures, thereby physically relieving the congested vessels of their overload of fluid. The fluid which is thus transuded through the coats of the vessels is serum, containing in solution more or less of fibrin. The seat of this imbibition is for the most part the subcutaneous areolar tissue, where it gives rise to œdema. I may instance scarlatina in some cases, erysipelas œdematosum, and erythema læve, as particular illustrations of this kind of tumefaction, although it will be found, upon close observation, to be much more extensively present among the exanthemata. This important phenomenon is not confined to the dermoid tissues; it occurs also in the mucous membrane, and sometimes with fatal consequences, as, for instance, in the laryngitis of scarlatina and rubcola, where it is apt to induce œdema of the glottis.

"Besides the œdema resulting from serous infiltration into the subdermoid tissues, it may happen that the transudation occurs also in the tissue of the dermis itself, in which case the skin presents a red, bloated, and brawn-like appearance, as in some forms of erysipelas. Or again, not confined to the subdermoid and dermoid tissues, the serous fluid may, after the repletion of those textures, be effused upon the surface of the dermis, and raise the epidermis in the form of vesicles and bullæ, as we frequently see to be the case in common erysipelas. This character associates erysipelas with the third natural group of diseases of the skin—namely, with inflammation of the dermis, combined with serous effusion upon its surface, including the orders Bullæ and Vesiculæ of Willan."

matter of fluor albus, and of gonorrhœa, by the dribbling of the urine, or escape of the fœces, by the flow of the tears, of the mucus of the nose, &c. In the intertrigo *podicis* of new-born infants, or in that which sometimes occurs about the groins and upper parts of the thighs in women who neglect proper attention to cleanliness, a sero-purulent fluid of a faint and disagreeable smell, accompanied by severe itching, often exudes for several days at a time from the inflamed surface of the skin. If this affection continues unchecked, and the causes that first produced it be allowed to continue, the skin becomes hard, and presents chaps of different depths, indicated by red lines traversing the moist and grayish-white coloured surface of the affected parts. When intertrigo appears between the toes, on the vulva, the prepuce, the margin of the anus, &c., these parts are always affected sooner or later with chaps and excoriations.

Dr. Ehrenberg<sup>1</sup> has given an account of a remarkable variety of intertrigo which attacked all hands on board of a vessel in the Red Sea. The skin of the scrotum was much inflamed, very painful, and at the same time greatly relaxed; a purulent secretion exuded from its whole surface; the disease disappeared as soon as the crew disembarked; but returned often and suddenly on the men again rejoining the ship. The Arabs suffered less than the Turks.

In infants at the breast ill-tended, and dressed with linen impregnated with urine and fœces, spots of erythema are often observed on the buttocks, the upper parts of the thighs, and on the scrotum, which are of a bright red colour, without any elevation of the surfaces attacked. The skin thus inflamed is hotter than in other parts of the body; the subcutaneous cellular tissue is not swelled, but the pulse is sometimes frequent. Children also while teething, have often spots of a bright red colour on the cheeks, which are hot but unaccompanied with tumefaction of the subjacent cellular tissue. There is at the same time heat of the mouth, pain and swelling of the gums, dribbling of the saliva, and the disposition to be constantly chewing. These red spots, at first merely accidental and temporary, sometimes end by becoming fixed; and then the heat and redness having subsided, the skin of the cheeks is left rough and chapped.

Prolonged walking or riding, constant pressure, by lying or otherwise on the same place (eryth. *paratrimma*), the prick of a needle, or the sting of an insect (eryth. *a punctura*), the morbid distension of the skin from œdema or anasarca (eryth. *læve*, Willan), the neighbourhood of a pustular or vesicular inflammation, or of an ulcer or a wound, all frequently cause this superficial inflammation of the skin, which differs from intertrigo in nothing but being unaccompanied by any morbid secretion.

2d. *Erythema papulatum* (Willan). This shows itself most frequently in females and young people, commonly on the back of the hands, on the neck, the face, the breast, the arms and forearms. The small red spots that characterize it are irregularly rounded and seldom exceed the size of a small lentil, or a large split-pea; they are slightly prominent, and as it were papular; of a bright red at the commencement, they soon assume a violet hue, particularly about their centres; they disappear almost entirely under the pressure of the finger. This eruption is commonly enough preceded by some degree of fever and sense of lassitude and weakness, by anorexia, and pains in the limbs. It sometimes shows itself in individuals labouring under acute rheumatism (*rheumatic eruptive fever*). The spots may be numerous, and by their junction form irregular groups of variable, sometimes of considerable, extent; within a day or two they sink to the level of the skin that surrounds them, and the redness itself disappears after continuing one or two weeks most generally without any perceptible desquamation.

3d. *Erythema tuberculatum* differs from the preceding variety in the occurrence between the papular-looking patches, of numbers of small, slightly prominent tumours, which sink down within a week, whilst the patches disappear more slowly, becoming livid and only vanishing after a week more. The erythema tuberculatum is preceded by fever, and accompanied, during its course, by general uneasiness and sleepless nights.

4th. In females, children, and young persons of weakly constitution and lymphatic temperament, another variety of erythema is rather

<sup>1</sup> Bulletin des Sciences médicales de Férussac, t. xiii. p. 232.

frequently observed—the erythema *nodosum* of Willan. General uneasiness, depression, and slight fever precede by a few days, or accompany the evolution of this eruption, which commonly appears on the arms and fore parts of the legs, under the form of red oval spots, slightly elevated in the centre, and varying in extent from a few lines to an inch and a half in their greatest diameter. By passing the hand along these spots, they are felt to form true elevations on the skin. These small red and painful tumours, the greater diameters of which are parallel to the trunk when they occur on the legs, seem hastening to suppuration; but their size soon diminishes; a bluish colour takes the place of their primary red tint, and they are resolved in the space of ten or twelve days, leaving behind them bluish or yellowish stains, as if the skin had been bruised. I have seen this species of erythema come on during the course of a rheumatic attack, having been preceded by very severe pain.

5th. The erythema *marginatum* is characterized by circular patches of a livid red, from half an inch to an inch in diameter, the circumference of which is distinctly separated from the healthy skin, raised, prominent, and slightly papular; their shining surface appears vesicular, but there is no actual effusion of serum beneath the cuticle. These spots, which may be preceded or accompanied by febrile symptoms, appear on all parts of the body, on the limbs, the face, the hairy scalp, and even on the conjunctiva.

6th. The patches of erythema sometimes form complete circles, the centres of which are healthy (eryth. *circinnatum*). The circular form of this variety seems to assimilate it to the herpes circinnatus, but it differs essentially from this disease in the absence of vesicles as well as in its progress and duration. It is still farther removed from the rings which are observed in the train of lichen circumscripatus, and of lepra, the cure of which diseases has commenced and gone on from the centres towards the circumference of the patches.

7th. Erythema *fugax* is the title given to that variety in which the redness is greatly diffused, always superficial, without appreciable swelling of the skin or subcutaneous cellular membrane, and which occurs unqually spread over the different regions of the body. This red colour of the integuments often differs little from the natural hue; but the skin is dry, and the heat of surface always higher than the proper temperature of the body. Both the arms of an adult labouring under doli-enteritis or furunculous inflammation of the bowels were observed on the day of his reception into La Charité to be of nearly as vivid a red as is observed in scarlatina; I caused him to be bled; and in thirty-six hours the redness had disappeared. This eruption may occur in an intermittent form, or appear and disappear under the influence of febrile exacerbations or paroxysms. When it happens towards the end of serious disorders, all traces of it vanish after death, and sometimes also on the approach of dissolution. This form of erythema is usually followed by desquamation of the cuticle, and occasionally, when it has continued long, by the loss of the hair; phenomena which do not occur till a week or a fortnight after the disappearance of the redness of the integuments.

219. *Chronic erythemata*. The workmen who use putrid urine in cleansing and whitening woolen cloths, bricklayers and masons who handle quicklime, miners and smelters employed in extracting lead and copper from their ores, blacksmiths and others exposed habitually to intense heats, are often attacked with chronic exanthemata of the hands. The skin first red, then dry and scaly, becomes hard, chaps, and is never bent without increasing the cracks, which usually cross the palm transversely betwixt the thumb and forefinger. The skin is rarely cleft through its whole thickness; the edges of the crevices are hard, and their bottoms often bleed, especially in the winter season.

Chronic erythema and chaps of the feet are only seen in those persons who walk about with these parts uncovered, or who go without stockings and neglect proper cleanliness. When the feet are chapped, the cracks run across the heels, along the lines of the sole, or between the toes.

The lips also have their erythemata, and are often chapped, especially, in the opposite extremes of intense cold or excessive heat, or during the continuance of a very dry and parching state of the air.

In women nursing, especially for the first time, the repeated application of the child and its eager suction, often excite erythematous inflammation of the nipple, which sometimes runs so high as to force

the mother to give up suckling, each visit of the infant causing intolerable pain, followed by sleeplessness and fever. The chaps that follow have been seen surrounding the base of the nipple, and penetrating so deep as to cause this part to be detached altogether, an event which is usually succeeded by ulceration to a greater or less extent of the mamma.

Pregnant women, too, during the last months of gestation, when the integuments of the abdomen are suffering the greatest distension, now and then suffer from *redness* and *chapping* of the skin of the belly. The same thing happens in the same place and also in the legs of those who are suffering under dropsy.

The chaps of the verge of the anus may be the effect of erythema and other chronic inflammations of the rectum, or of some excessive distension of this opening caused by the excretion of hard and bulky feces. Chaps in this situation are often complicated with a spasmodic stricture of the anus.

Chaps of the *prepuce* are sometimes caused by the erection of the penis, which distends and splits the part when the opening is narrow.

Chapping of the vulva is almost always consecutive to lichen agrius, or to eczema rubrum developed in the genital parts; or otherwise it succeeds to difficult labours, without being sensibly preceded by erythema.

220. Chronic erythema, arising independently of external causes, is often a very obstinate pyretic affection; such is that which is vulgarly designated under the name of *fiery spots*, (*taches de feu*), which very often co-exists with rosacea, and succeeds it even more frequently. This variety of erythema is habitually subject to return, and is characterized by a red colour of the skin, which becomes pale under the finger, and by slight vascular arborizations or net-works that spread upon the cheeks, over the cheek-bones, and on the alæ of the nose. It is attended with pruritis, and a feeling of heat and tension, especially when there happens to be any accidental determination of blood to the head or face. Lastly, at the period of the epidemic disease which prevailed at Paris in 1829, I had occasion to observe an immense number of chronic erythematous inflammations of the palms of the hands and soles of the feet; but they were accompanied by so remarkable an epidemic secretion that their description must be included under that of pityriasis *rubra*, or rather of the epidemic disease of which they constituted one of the principal features. (See in the Vocabulary, under the word *Acro-dynia*.)

221. *Diagnosis*.—A previous eruption of vesicles, a more abundant and more serous secretion, and a greater obstinacy of inflammation, distinguish *eczema* of the ear, of the genital organs, of the verge of the anus, of the umbilicus, &c., from *intertrigo* of the same parts. As to the *blenorragia* and *intertrigos* of the navel, especially, account must be taken not only of the appearance of the inflammation, but farther of its cause, to keep us from mistaking these for other affections.

It may be difficult to distinguish the *papular* and *passing* forms of erythema, from some varieties of roseola, although this last disease in its progress bears a greater analogy to the class of eruptive fevers. Urticaria differs from papular erythema by the greater breadth of its spots, by the peculiar itchiness that accompanies it, by its irregular progress, which is often fleeting and intermittent, and by the absence of the violet or livid hue which is observed in erythema. In lichen *urticatus* the papulæ are less in size, rounder and firmer; their colour is not nearly so deep as that of the patches of papular erythema; as in urticaria there is always a great degree of itching present, a symptom which in strophulus is so troublesome as entirely to deprive children of sleep. I have, in fine, seen the papular erythema appearing on the forehead, on the face, and on the breast, after two or three days of feverish symptoms, in such a manner as greatly to stimulate the elevations and spots that precede the development of the pustules of small-pox.

At first sight the violet spots of the papular erythema might be mistaken for syphilitic patches in their first stage; but the progress of the latter, were they accompanied by no other symptom of a venereal taint, would suffice to distinguish them, if even they failed to present the shining appearance and coppery or grayish colour that so peculiarly distinguish them. When these two eruptions occur together in the same patient, the determination of the patches belonging to each requires some discrimination and not a little care.

The very common complication of chronic erythema of the face with rosacea, cannot excuse Peter Frank for having united two diseases so very distinct under the same description. In fact, the erythema is an exanthematous affection, whilst rosacea is decidedly pustular. It is, also, of great importance to distinguish, by means of a careful examination into the state of the different organs, the idiopathic erythema of the buttocks, verge of the anus, scrotum, and lower limbs, caused by filthiness, from that which often coincides in newly-born infants with acute or chronic inflammatory affections of the mucous membranes of the cæcum and colon, and which has very frequently the same appearance. A like redness about the buttocks and genital organs of the infant has also been mistaken, by superficial observers, for symptoms of a syphilitic affection; at the present time such mistakes are, happily, very rare. This variety of erythema, the only one that can be confounded with erysipelas, differs from it by the absence of tumefaction in the subcutaneous cellular membrane. As to the other varieties of erythema, erysipelas is precisely the form of skin disease with which they are least likely to be confounded. The chaps consequent on eczema, lichen, and syphilitic affections of the vulva, margin of the anus, ears and nipples, and the cracks produced by pityriasis or psoriasis of the palms of the hands and soles of the feet, differ from those observed in the chronic erythemata, by being preceded or accompanied by other elementary and characteristic conditions.

Erythema *nodosum* cannot be confounded with any other variety of exanthema: it differs entirely from roseola by the deep tumefaction that characterizes it. It sometimes accompanies attacks of rheumatism. Erythema *annulatum* differs from annular herpes by not being surmounted by vesicles. To the erythema *lave*, some artificial exanthematic inflammations might with propriety be connected.

222. *Prognosis*.—Acute erythemata, whatever their extent, are not in themselves serious complaints, and their duration does not, generally, exceed two or three weeks. Chronic erythemata, produced and kept up by external causes, get well rapidly under proper treatment; but the cure of very old erythemata, that have come on without any evident physical or chemical cause, is as difficult as it is uncertain.

223. *Treatment*.—When the varieties of acute erythema are apyretic, and without complication, they get well of themselves in the space of a week or two. When they are painful or accompanied by fever, they must be treated by means of emollients, by baths and fomentations of the decoction of althea or of bran, gently warmed or almost cold; by general bleeding, if the disease extends to the conjunctiva, and if the patient is of a robust constitution or subject to epistaxis. The diet ought to be cooling; and diluents, such as lemonade, whey, barley-water, &c., ought to be freely used.

The pain and morbid secretion in the intertrigo of children are often diminished by attention to cleanliness, by changing the napkins frequently, and by powdering the inflamed and chapped skin well, after having bathed and cleansed the parts by means of a mucilaginous fomentation.

In adults, when intertrigo *ani* appears to be the effect of riding, or that of the tops of the thigh follows much walking, the skin must be rubbed with tallow softened by heat. When the erythema is produced by pressure or the weight of the body, (eryth. paratrimma, Sauvages,) the part must be covered with some soft or soothing plaster, and the weight of the body and the pressure thrown as much as possible upon other regions. This species of erythema is often accompanied by cutaneous or subcutaneous ecchymosis, a two-fold alteration that is frequently followed by gangrene in patients affected with dothineritis, and in elderly persons. To prevent this unfortunate termination, the decoction of bark, solutions of alum, and infusions of oak bark are sometimes had recourse to with success.

The erythema that is produced by the distension of the skin in œdema and anasarca, is to be treated by cold mucilaginous lotions, by rest, a horizontal position of the limbs, the support of a bandage, and but rarely by the local abstraction of blood, which, however, is sometimes a good measure; in addition to these, the treatment proper in dropsical complaints must be enforced.

The lesions that precede or accompany the development of acute erythematous inflammations, present peculiar indications. General blood-letting is always required at the beginning of a rheumatic eruptive fever; local bleedings from the abdomen or margin of the anus, are often useful in cases of gastro-enteritis, or of cæco-colitis in infants at the breast, attacked at the same time with erythematous affections of the buttocks and thighs.

224. *Chronic erythemata* of the hands and feet, caused by external circumstances, are to be met by warm fomentations and bathing, by soothing cataplasms, and sometimes by vapour baths. Liniments, consisting of oil or lard, to which the oxide of zinc, in the proportion of an eighth [or a little camphor], is sometimes added, are usual remedies for chapped hands and feet. The affected parts are to be smeared, and a glove or leather sock to be worn night and day, in order to restore to the integuments the softness and pliancy they have lost.

Chaps of the nipples are to be treated with mucilaginous fomentations, as decoction of marsh-mallows, poppy-heads, &c., with the addition of a certain quantity of acetate of lead or sulphate of zinc.—The nipple is to be kept anointed with any mild unguent, with which, when the pain is very severe, a small quantity of opium may be mixed. [The nitrate of silver in solution, or mixed with spermaceti ointment, often proves the best of all remedies in this troublesome and, at times, serious complaint.] The nipple must be gently washed with tepid water, before the infant is applied, when nursing is not given up entirely. All remedies, however, commonly prove unavailing, unless the mother consents to deprive the child of its milk for some days at least, as, without this measure, the repeated application of the mouth causes so much irritation that the chaps are continually renewed. The mammaræ are best depleted by the application of a proper cupping-glass furnished with a syringe, or by steaming the breasts over hot water. Should we succeed in healing up the excoriations in this way, suckling may be tried again, provided the secretion of milk has not disappeared.

Chapping of the nipples may sometimes be prevented by habituating the parts to a certain measure of irritation, by gentle suction, previous to delivery, and keeping them covered with a shield of elastic gum, [bee's-wax or silver. The yellow bee's-wax shield to prevent the pressure of the clothes, the application of the nitrate of silver ointment (gr. iv to gr. viii, to ʒss of unguent. cetac. or lard) and the use of the shield and prepared cow's teat, will, in a considerable number of cases, do away with the necessity of even suspending suckling for a day, much more of giving it up altogether]. (a)

Excoriations of the *prepuce* require the operation for phymosis, when they are owing to the distension and traction of the part during the erection of the penis.

Excoriations of the *anus* require the use of soothing suppositories, hip baths, and bland injections; when the affection is complicated with spasmodic stricture of the rectum, it commonly yields to gelatinous fomentations or stuping, but is cured more certainly and speedily by the double incision proposed by Boyer.

Excoriations of the legs, complicated with œdema and petechiæ, are best treated by the horizontal position of the limbs, by the pressure of a light bandage, and when the skin is very much inflamed, even by the abstraction of blood locally.

Chaps and excoriations of the toes require the feet to be frequently washed, and a piece of soft lint to be interposed twice a day, between the several digits.

The superficial excoriations to which new-born children are sub-

(a) Small benefit will be derived from topical remedies in this troublesome and often exceedingly painful affection, unless the so frequently associated febrile irritation and derangement of the digestive function be removed. This is done by purgatives, alternating with magnesia and the alkalis. Of the first, calomel, followed by castor-oil, Epsom salts, or rhubarb and magnesia, with compound powder of jalap, answers a good purpose.

When stimulating washes are indicated, I have derived most benefit, in some cases, from the solution of sub-borate of soda in water and alcohol, and in others, from the fluid chloride of soda of the shops, diluted with equal parts of water.

ject, get rapidly well by attention to cleanliness alone, by the use of baths and fomentations, and the free application of powder to the inflamed parts. [If they are obstinate, some weak metallic wash (as zinci sulph. gr. xii to aq. font. vel rosæ ʒiv) heals them immediately.]

As to those chronic erythemata that are independent of outward causes, and fiery spots of the face (*taches de feu*), they often resist every curative means attempted. They have occasionally been successfully treated by the use of baths and steaming, alternated with the local administration of sulphureous vapours; in some cases, too, the cure has appeared to be aided by the use of purgatives.

#### *Historical Notices and Cases of Erythema.*

225. Erythema has been differently and often imperfectly described in books of pathology. One of its varieties (*redness about the margin of the anus*), has been signalized as a disease peculiar to childhood; another chronic erythema has been entitled *dartre erythemoïde*, thus mixing it up with vesicular and scaly diseases; and a third, erythema *diffusum*, has been confounded with erysipelas.—Cullen erred when he asserted that erythema was always without concomitant or secondary fever. By regarding it as the lowest degree of erysipelas, Callisen shows that he was unacquainted with its principal varieties, though they are well described by Willan. Pellagra, which belongs to the order of squamous affections; and acrodynia, which, in many respects, bears a strong analogy to pellagra; burns and frost-bites, which may appear under the bullous and gangrenous forms; the hydrargyria, whose form is vesicular, have all of late, but improperly, been included among the erythemata. Cases of the principal varieties of this exanthematous eruption, may be found in various special and periodical publications.<sup>1</sup>

CASE I. *Symptomatic Erythema of the buttocks and thighs: cæco colitis.* The daughter of M. \*\*\*\*, six months old, at the beginning of Nov., 1824, presented all the symptoms of acute cæco-cæcolitis or inflammation of the mucous membrane of the cæcum and colon: she had frequent liquid, glairy, sour, and at times sanguinolent motions; pain was evidently excited by pressure along the course of the colon, which was not the case in the districts occupied by the other viscera of the abdomen; the great intestines were distended with flatus which was often expelled; there were fever and loss of appetite: the tongue was nearly natural. At the same time a number of red spots from half an inch to two inches in diameter, of an oval or irregular shape, strongly defined, but not prominent, appeared on the upper parts of the thighs, around the trochanters, and in the inguinal and ischiatic regions. The subcutaneous cellular substance did not participate in the inflammation of the skin.—The symptoms all yielded within twelve days to the application of leeches to the anus, to the use of the warm bath and of emollient cataplasms, to injections of small quantities of decoction of marsh-mallows and of poppy-heads into the rectum, and to the antiphlogistic regimen generally. A month afterwards there was a fresh attack of intestinal inflammation, and a new eruption of these erythematic spots. The same plan of treatment was followed, and with the same success. The inflammatory affection of the great intestine has since recurred at intervals remote in various degrees from each other, and has always been accompanied by symptomatic spots of erythema on the hips and thighs; but the plan of treatment indicated, has always proved adequate to put an end to the disorder; and since the month of March, 1825, the child has thriven, and has always enjoyed good health.

CASE II. *Erythema marginatum; patches scattered over the face and surface of the body: Bronchitis.*—I. Bailliot, 26 years of age, of a sanguine temperament and strongly built, entered La Charité on the 13th of Feb., 1827. This patient had been eight days previously

attacked with the eruption for which he now sought assistance. It was characterized by spots of a red colour, which disappeared on pressure, of an irregular shape, of various sizes, slightly prominent, and not itchy. A certain number of these spots were seen on the forehead and nose; the right eyelid was red and slightly œdematous, the left was only injected in a very small district. Similar patches were observed on the dorsal aspects of the forearms, where they were larger than on the face, and also behind the ears. Their surface looked as if sown over with small white elevations; but on raising the epidermis with the point of a pin, it was seen that there was no fluid effused beneath it. Some of the patches appeared to be surmounted by accidental vesicles. The patches were often confluent, others were distinct, and from three-quarters of an inch to an inch in diameter. The chin was covered with solid red lumps, with little tubercles flattened on their summits, in the intervals between which the skin had its natural appearance. Similar elevations, but of less size, occurred in different parts of the cheeks and neck; the cuticle that covered these was shining. One of the lumps of the chin was covered with a yellow crust, produced by the drying of a vesicle. The lips, of unequal redness, seemed marbled; on each conjunctiva, there was a patch of a very vivid red, towards the inner angles of the eyes, which were weeping. On the fore parts of the legs spots were also visible of a less intense degree of redness than those of the face.

This erythema first showed itself upon the neck after two days of a violent cough and sense of lassitude. On the third day the patient took to his bed, since which time he has had shivering fits every evening; these continue all night. He complains of headache; the tongue is moist, without any redness of the edges, and is covered by a yellowish fur; he suffers from eructations and constipation, having had but one motion within the last eight days; the pulse is full, a little more frequent than in the healthy state; mucous rattle at the posterior part of the left lung—(*Venesectio ad ʒxii, mucilaginous lemonade for drink, and low diet prescribed*). Feb. 15th.—The blood was found strongly buffed; the patient was sweating profusely: the spots of the eruption were prominent and less red on the face; the cuticle appeared wrinkled on the surface of those behind the ears; some of the spots on the other parts were also of a less vivid red or livid hue. A few adventitious vesicles were observed full of serum. Feb. 16th.—The spots on the legs have faded; several of those on the face are white and shining, and on the lips they are paler and more collapsed. He complains less of headache, he sleeps better, the fever is diminished, and the expectoration is easy. Lemonade was continued as drink, emollient injections were prescribed, and better diet, broth or soup several times a day was allowed. 17th.—The patches of the forearms are becoming white towards their centres, and form a sort of ring; those of the right forearm have become confluent; those of the left are a little more extended; others, as those behind the ears, and on the right upper eyelid, have disappeared, or such as still remain form little islets surrounded by the white or rose-coloured skin; a slight desquamation is taking place about the root of the nose, and behind the left ear. The spots on the legs are shrunk. He sleeps well; the respiration and expectoration are easy, and the appetite has returned. 18.—The redness of the spots declines more and more; their prominence diminishes gradually, especially in the centre; the œdema of the eyelids is no longer visible; in a word, from this time forwards, the erythematous patches everywhere disappeared, and were succeeded by a slight desquamation, so that the patient left the hospital perfectly well on the 28th, after a fortnight's confinement.

CASE III. *Several varieties of erythema in the same individual.*—M. Dalivot, 21 years of age, entered the hôpital Saint Antoine, on the 4th of May, 1830. This young man, strong and well formed by nature, had never hitherto suffered from any disease of the skin. Within the last week, however, some red patches had appeared on the face, attended with itching which prevented him from sleeping. The digestive functions having been out of order, leeches had been applied to the epigastrium. On the 5th of May, the face, the upper and fore parts of the chest, and the legs presented an eruption of spots of a livid red colour, raised above the level of the skin, irregularly circumscribed, and not disappearing completely under the pressure of the finger. Some of these were as large as a sixpence, and rounded

Précis sur les maladies de la peau, t. i. p. 273 (Dartre erythemoïde).

in figure; others, the size of the hand, appeared slightly corrugated on their surface. Their circumference was shining and transparent as if fluid had been effused under the epidermis; but when this was pricked, nothing followed but a little blood; on the legs the spots were oval-shaped, deep-seated, as it were knotted, and of a violent tint. On the backs of both hands, and the dorsal aspect of both forearms the spots were papular, and of the size of small lentils. On the head, and amongst the hair, small elevations were felt. The patches were the seat of rather violent itching. The patient complained of headache, the eyes were somewhat bloodshot, the pulse was full and hard, the tongue white. The right side of the chest was less resonant than the left. No mention was made of pain in the epigastric region. He was bled to  $\frac{5}{2}$ ii, and put upon lemonade as a diluent. The 8th of May: the red patches are shrunk, their surface shows slight furfuræ, and their circumference no longer appears shining; the redness now disappears on pressure, and instead of hard risings along the legs, a number of brownish and yellowish marks alone remain. The patient left the hospital some days afterwards quite well.

CASE IV. *Papular and tubercular Erythema; Bronchitis; Rheumatism; eruptive rheumatic Fever.*—Marie Michaud, 22 years of age, a servant girl, of a soft and lymphatic constitution, has been unwell, during the last four months she has lived in Paris. Some days after coming into the hospital she observed red patches on different parts of her person; they are now distinct on both elbows and on the arms, and are of various sizes, from that of a sixpence to that of the palm of the hand. These patches are prominent, painful, and disappear under pressure, to reappear from their circumference towards their centre as soon as it is removed; their colour, generally red, is in some of a livid cast. The elbow joint appears swollen; motion there is difficult, and it is very painful to the touch. The appetite is gone, the breath disagreeable, the pulse frequent; sweating, no cough, the menses flowing. On the 1st of March, 1830, both elbows and both knees are swelled and painful; the former is half bent and cannot be straightened. The patient also suffers pain in the wrist, and a little in the fingers, which, however, she cannot move without the greatest suffering. The red patches observed last evening are in the same state; others of a smaller size—from that of a lentil to that of a six-penny-piece—have appeared on the thighs. They are projecting, smooth, and painful to the touch. The pulse is frequent and full; anorexia. (Two bleedings of  $\frac{5}{2}$ ii, each were practiced within the twenty-four hours. Mucilaginous drink.) 6th.—The wrists only are now painful; the red patches of the elbows have gone; several livid and bluish patches are disseminated over the limbs: cough; hissing and mucous rattle. The rheumatic pains continue; on the elbows and wrists the patches have a marbled appearance; the tongue is yellow, foul, and thickly coated; there has been vomiting; no passage of the bowels; pains in the belly; insomnia (thirty leeches to the epigastrium, two emollient injections, low diet). 8th.—Bluish marks replace the red patches; the left knee is painful, the wrists and elbows but slightly so (thirty leeches to the knee, a bath). 9th and 10th.—The patient still suffers in the knees and wrists, which are a little swollen; pains of the epigastrium and abdomen; tongue still coated and yellow (broth allowed, and the bath repeated). 11th.—The right knee is less painful; the appetite has returned (same diet). 17th.—The patient suffers less. (The baths are continued; better food.) 22d.—Convalescent. The patient discharged well on the 3d of April.

CASE V. *Papular, confluent and hemorrhagic Erythema.*—Bridoux, a shoemaker, 23 years of age, entered La Charité on the 1st of June, 1831. From a very early age he had been accustomed to be purged every spring; a measure which he had neglected this season. For several months he had been working very hard, rising at four o'clock in the morning, and going to bed at midnight; he had also been living worse than usual. His temperament might be characterized as lymphatic.

On the 31st of May, he had been in a violent passion; towards the evening of the same day, he felt his face puffed and hot, and a sense of itching in different parts of his body. Soon after, red patches appeared on the arms, the breast, the back, the belly, and lower limbs; these patches rose above the level of the skin; of small extent at first, they spread rapidly and became confluent in many districts. There was neither pain of the throat nor of the eyes: the night was disturbed.

June 1st.—The patient exposed himself to a current of cold air. At night the face was somewhat puffed, and of a general pale-reddish colour; all the rest of the surface of the body, especially the posterior region of the trunk, presented patches of greater or smaller magnitude, generally irregular in shape, evidently prominent to the eye, as well as sensibly so to the touch. The redness disappears on pressure and reappears again immediately. The patches are completely indolent. Since the morning he has had slight cough and soreness of throat; the tongue is moist and rather clean, the respiration is natural, pulse 96, (tisan with mucilage and honey, syrup of diacodium half an ounce). June 2d.—The night tranquil, sleep only interrupted by the cough. The patches on the whole of the posterior region of the trunk are shriveled, and their former vivid red colour is replaced by a pale violet tint. On various points corresponding to the primary patches, and on the spaces that separated them, spots, evidently hemorrhagic, and similar to those of purpura, have appeared; these neither disappear nor diminish in intensity by pressure. On the belly and limbs, the red colour and prominence of the patches observed the preceding evening remain. Pulse 108 and rather hard—(bleeding to  $\frac{5}{2}$ ii, mucilaginous lemonade, low diet.) By seven o'clock in the evening of the same day, the patches of the trunk are shrunk; a violet hue has succeeded the bright red that characterized them in the morning. On the legs and thighs, the patches still preserve their prominence and their red colour, though in a less degree. The heat of surface has increased; it is particularly great on the back, where a portion of the skin that has hitherto remained white has acquired a livid hue, which disappears under the pressure of the finger. On other regions, large patches of a violet colour are observed, which do not vanish under pressure. The blood drawn is not buffy; no cough; pulse from 86 to 100; the patient can close his hands, which he could not do last evening on account of the swelling and stiffness of the fingers. June 3d.—Ecchymoses are seen stretching in lines or in irregular patches upon the shoulders and loins. The general livid colour of the integuments of the back disappears on pressure. On this ground, isolated maculæ appear scattered here and there, having the colour of ecchymoses. The sanguineous suffusion is especially conspicuous on the back: the maculæ, very closely set and large, are most numerous on the thighs, the loins, the flanks and belly; the arms are freer. These stains disappear completely under the pressure of the finger. June 4.—A pale yellow colour begins to be visible amidst the general livid hue of the back. Several of the confluent stains, too, present an appearance of commencing absorption towards their centre, the yellow tint of which parts is in strong contrast with the purple of their circumference. The countenance is natural; the appetite has returned. June 5 and 6.—The livid colour continues to yield to the yellow, and by the 7th the skin, except on the thighs, had regained its natural appearance; better food was now allowed, and on the 9th the patient left the hospital cured.

CASE VI. *Œdema of the legs; petechiæ; chaps.*—Fr. Martin, 63 years of age, and labouring under these symptoms, was received into La Pitié on the 5th of August, 1826. In the course of the year 1822, after undergoing great fatigue, he had been affected in a similar way, and been cured by simple lotions with cold water. He had, however, for 15 months afterwards, suffered with chapped hands. Employed for the last 14 days in a species of work that fatigued him greatly, his legs became œdematous, so as to pit under the finger; red patches, which disappeared on pressure, at the same time appeared on the insides of the legs; besides these patches, which now form groups in different places, a great number of petechiæ, disposed in clusters or running in longitudinal or circular lines, are visible, principally on the fore parts of the legs; the cuticle seems raised over some of these petechiæ; in some places the blood has even traversed the skin, and the tops of the petechiæ are then covered with a small drop of dried blood. The skin of the legs is farther divided by numbers of irregular and mostly transverse chaps or cracks, half a line in breadth and several lines in length; some of these are deep, and a yellow transparent viscid fluid is poured out between their edges, which forms linear concretions along the legs; the feet are œdematous, but not otherwise affected.

Whilst under treatment, 60 leeches were applied to the legs, which were covered in the intervals with emollient poultices. The œdema,

petechiæ, and chaps amended gradually, and the patient quitted the hospital on the 15th of August, 1826.

CASE VII. *Chronic Erythema of the nose and of the malar regions preceded by habitual Epistaxis, and by Erysipelas of the face.*—Baptiste, 30 years of age, had suffered repeated attacks of crsipelas and boils, and had had itch, besides two gonorrhœas, which lasted six months each, between 1800 and 1818. He has also been subject, from his infancy till two years and a half ago, to bleeding from the nose, so incessant that he never in all that time sent an handkerchief to be washed that was not stained with blood. He then became affected with deafness, which lasted two months and got well without any treatment. It was now for the first time that he perceived some red spots upon the nose and cheeks, which have since slowly increased in size. On the 20th of May, 1828, I noted three of these vulgarly styled *fiery spots* (*taches de feu*) on different parts of the face, two on the cheeks, the third on the base of the nose. These spots, of a deep-red colour and well defined, are not hot, except when the blood mounts to the head; he does not complain of their itching at present, and when he has, he has only passed his hand over without scratching them. By compressing the skin of the nose between the fingers, a few serous points are forced out apparently from the follicles. The skin has never been greasy, neither has there been any transudation of red fluid, as in eczema rubrum, nor any appearance of pustules, as in rosacea, nor of papulæ, as in lichen. Before consulting me, the patient had made use of several ointments of the composition of which he is ignorant. (*Ordered to be bled, whey for drink, lotions with almond emulsion, milk diet.*) After the bleeding, which was copious, the red colour of the skin disappeared for a while, but soon returned. I ordered six leeches to be applied thrice within the nostrils, after the application of which, the patient complained of greater heat in the cheeks. For the last two months he has had a blister on the arm, which does not appear to have had any influence on the progress of the exanthematous affection. Purgatives and sulphureous lotions had the effect of causing a notable diminution in the eruption; to such an extent, indeed, that the patient, despairing of a radical cure, gave up paying farther particular attention to his complaint.

CASE VIII. *Chronic erythema of the hand and forearm.*<sup>1</sup>—M. F\*\*\*\*, nearly 46 years of age, of a very hasty temper, and habitually given to disputation, after several days of unremitting exertion, perceived a sudden eruption of rather large patches, of a bright-red colour, which, however, uniting together, soon assumed a livid appearance, upon the back of the left hand and forearm of the same side. As he was subject to an eruption of this kind, which showed itself on different places, he betook himself to the use of diluents, baths, fomentations, strict regimen, &c., and abandoned his labours,—a very rational plan of treatment, which he was accustomed to pursue with success in former instances. But after the lapse of three weeks, the disease, which used to disappear at the end of 12 or 14 days, had attained a great degree of severity, and I was consulted. The eruption now extended from near the elbow to the first phalanges of the fingers; it was slightly elevated, and almost of the colour of wine-lees, accompanied with much itching, which the patient had great difficulty to prevent himself from trying to appease by scratching; the surface was rough, soft, and presented several islets of healthy skin. I ordered the application of a number of leeches around the disease, and to the points in the midst of it that were unaffected, a practice that was followed by very little relief. I directed two vapour baths, to be followed by the local administration of the hydro-sulphurated vapour. The appearance of the eruption was by this means quickly changed, and by persevering in the treatment of ten days, the disease was subsided entirely.

ERYSIPELAS.

Vocab. *Erysipelas, Ignis sacer, Rosa volatica, Rose, St. Anthony's Fire.*

226. Erysipelas is a spreading non-contagious, exanthematic inflammation, characterized by a red colour of the skin, with swelling

of the subcutaneous cellular tissue, commonly ending in resolution and desquamation, sometimes in suppuration, seldom in gangrene.

227. *Causes.*—Erysipelas may be developed under the influence of appreciable causes, such as filthiness, rude and repeated frictions, exposure to violent heat, the contact of poisonous plants, of certain insects, or of the juices or fluids excreted from their bodies; the application of topical irritants, pricking with instruments impregnated with animal fluids in a state of corruption, and external injuries generally,—a contused wound, a surgical operation, the vaccine and variolous inoculation, &c. Among other well-authenticated causes of the disease, we must also include certain influences engendered by the nervous system under paroxysms of passion, profound grief, &c. As to bad and corrupted food, high seasoning, the abuse of spirituous liquors, and indulgence in the pleasures of the table, these may certainly give cause for the development of erysipelas, but there is nothing to prove that they occasion this more frequently than any other disease. The etiology, however, of a vast number of cases of erysipelas, is involved in the greatest obscurity. It is known that the appearance of the disease coincides with a buffy state of the blood, analogous to that observed in acute rheumatism; and it is not less certain that diffused and flitting erysipelas, coming on in patients worn out by some chronic inflammation, is the precursor of approaching dissolution; the observer confirms these facts every day without being able to ascertain their causes. Other circumstances, again, do not admit of so rigorous a construction. "There are seasons," Mr. Calmeil writes to me in 1828, "when erysipelas spreads universally among the insane, and causes a suspension of the revulsive measures which form, as it were, the bases of our treatment in cases of mental alienation. The application of a seton, or a moxa, or a blister, is then followed by erysipelatous inflammation; a superficial wound of the skin has the same consequences; the slightest stroke, the opening of a vein, the application of a leech, all are followed by erysipelas. The present year (1828) has been particularly remarkable in this respect; during the last six months, the infirmaries have been filled with the insane labouring under erysipelas. The disease begins on any part of the body, sometimes on a healthy part of the skin, but most frequently in the vicinity of an issue. After four or five days of treatment, it extends to the surrounding parts, and in the space of 20, 30, 40, or 50 days, it has spread over the whole, or nearly the whole, of the surface of the body. Treatment by compression did no good; the bites of leeches became new centres for the disease; many patients were reduced to extremity and several died. In preceding years, I have seen a similar epidemic constitution prevailing in the asylum at Charenton, but never to the same extent as at present." Facts of the same description have been observed at the Bicetre, Salpêtrière, Saint Louis, La Charité, [and in almost all other great hospitals,] at certain times, and during certain periods, when the disease of erysipelas occurs so frequently as to assume the character of an epidemic.

It has been said that erysipelas was capable of being transmitted from one individual to another by contagion. This opinion, lately revived by Weatherhead and by Dr. Wells, and which a case observed by Costallat seems to countenance, has arisen, perhaps, from two or more individuals exposed to the same influences, having been successively or simultaneously attacked by the disease. Erysipelas is more frequent during the spring-time and autumn than at any other season. It sometimes recurs in the same individuals at determinate intervals, variously remote from each other; some have one or two attacks every year, just as others suffer from eczema and lichen. In amenorrhœa, erysipelas sometimes appears periodically at the times when the menses ought to flow; men are less subject to such attacks and relapses than women. The disease, arising from external causes, attacks, in preference, persons of a fine and delicate skin.

228. *Symptoms.*—When erysipelas is the effect of causes that have not acted directly on the skin, certain morbid phenomena common to a great number of acute diseases, are almost constantly observed before the attack; such as headache, pain in the epigastric region, nausea, bitter taste of the mouth, constipation, slight shivering fits, hardness and increased frequency of the pulse, &c.—the *erysipelatous fever* of Hoffman.

1. Towards the second or third day of this febrile state, *simple erysipelas* is proclaimed by the following symptoms (*initium*): slight and

<sup>1</sup> Rapou. *Traité de la methode fumigatoire*, t. ii. p. 27.

irregularly circumscribed tumefaction in some part of the integuments, very frequently of the face; redness of the skin, with a tinge of yellow, and sometimes of blue, disappearing on pressure, reappearing immediately the finger is removed, sharp and pricking pains in the part affected, accompanied by smarting, and a sensation of dry and burning heat. These symptoms and the febrile condition increase in severity to the third or fourth day (*augmentum*), and continue for about the same period with the same degree of intensity (*status*). The inflamed skin sometimes becomes covered with vesicles analogous to those of *eczema* or *miliaria* (*erysipelas miliaris*). Sometimes, also, bullæ or blebs appear on different parts of the inflamed surface (*erysipelas phlyctenodes*). These blebs, isolated or confluent and similar to the blisters produced by a scald, break on the very day of their appearance, and most commonly towards the fifth or sixth day of the disease; the fluid they contain dries and forms hard yellowish crusts which subsequently become brown or black, and are a line, or even several lines, in thickness.

The most favourable termination of erysipelas is in resolution; an event which is indicated by the symptoms, after having continued for three or four days in all their intensity, beginning to subside (*decrementum*); and the certainty of the issue is known by the gradual disappearance of the redness, the pain, the heat and the tumefaction. The cuticle then falls off in scales, the crusts are detached, and there is soon nothing remaining but a slight pastiness, which is not long of going also. The process of desquamation is more or less apparent according to the nature of the parts attacked with erysipelas, and its intensity. Mr. Wilson was accustomed to exhibit every season for several successive years, a patient to his pupils who was subject to annual attacks of erysipelas, at the end of which, the cuticle of the hands was entirely detached in the form of a glove, and that of the feet, like a bag. A case of the same kind is recorded in the sixth volume of the *Philosophical Transactions*.<sup>1</sup>

Of all the forms of inflammation to which the integuments are subject erysipelas is that which has the greatest disposition to vanish suddenly, an event that is often followed by its appearance in some other part of the body (*erysipelas erratica, vel ambulans*), or the development of inflammation in some more important organ (*erysipelas metastatica*). Thus it has been seen extending successively from the hairy scalp, the forehead and the face, to the neck, and then to the shoulders, whilst the face and scalp were freed from it; or otherwise, appearing momentarily on the face, and, vanishing thence, replaced by a mortal affection of the brain or its membranes.

Fever, heat of surface, sleeplessness, and gastric disturbance commonly attend in the train of erysipelas; more intense as the inflammation advances, the symptoms decline in the same proportion as the inflammation subsides towards the seventh or eighth day of the disease. The termination at this period is sometimes announced by a sediment in the urine, by the bowels becoming open, or by the occurrence of some slight hemorrhage.

2. *Phlegmonous erysipelas*, as its name implies, partakes of the nature of phlegmon and of erysipelas at the same time; the skin and the subcutaneous cellular substance may be alone affected, or the inflammation may reach the sub-aponeurotic cellular tissue, cause the most alarming symptoms, and bring the life of the patient into jeopardy, if he be not promptly and effectually aided. The various shades of this species of erysipelas may be arranged under three different degrees according to the intensity of the morbid phenomena. 1st degree.—At the outset, anxiety, followed by smarting and redness in the part about to be affected with inflammation; anon a sense of burning in the inflamed part, a bright red colour of the skin, diminishing insensibly round the circumference of the seat of disease, and disappearing for an instant on pressure being made with the finger, after which the point compressed regains more slowly than in simple erysipelas both its morbid colour and its former level. The portion of integuments affected, raised by the swelling of the subcutaneous cellular tissue, forms a large tumour, hard, and penetrating deeply; the pain becomes pungent, the heat burning, the lymphatic glands inflamed, and a considerable degree of fever is present. If, towards the fifth or sixth day, the skin is observed to become less red, less tense, to be covered

with branny scales, and the subcutaneous cellular tissue to resume its original volume, the phlegmonous erysipelas will end in resolution, or in effusion, the fluid of which will be absorbed after a few days. If, on the contrary, the pain becomes pulsative, symptoms of suppuration will not be long of showing themselves. The abscesses that follow, opened naturally or by an incision, are found filled with laudable pus and soon heal up. 2d degree.—The phlegmonous erysipelas is of larger extent; the degree of redness, of heat, of suffering, and of fever all greater in amount. Between the sixth and the ninth day, if the inflammation is left to itself, purulent deposits are formed here and there under the skin, and even in the spaces between the muscles: when these are opened, sphacelated shreds of cellular membrane are discharged along with a quantity of pus; sinuses and fistulous passages are formed and pour out an ichorous and fetid matter. Occasionally, the skin, detached from the parts beneath and very thin, becomes grayish in colour, and folds in upon the edges of the ulcerous cavities. The mucous membrane of the stomach and intestines inflames, and the patient often sinks exhausted by fever, diarrhœa, and the copious discharge that takes place from the subcutaneous cellular membrane. 3d degree.—The symptoms in this last degree are even more violent from the outset. Within the space of two or three days, the erysipelas attains its greatest intensity; the skin, smooth, tense, and shining, is of a bright red colour, and scarcely preserves for an instant the impression of the finger. The distress of the patient increases: his pulse is hard and frequent; he suffers great pain; tossing about in his bed, he gets no sleep, becomes delirious, and is parched with thirst; all these symptoms are even aggravated towards evening. About the fifth or sixth day, the inflamed skin loses its sensibility, puts on a livid hue, becomes softened and covered with phlyctenæ filled with reddish or blackish serum. Ecchymoses and eschars form (*gangrenous erysipelas*), at the same time that several abscesses are produced. Under the most favourable circumstances, these sphacelated parts are thrown off and the sores slowly heal; but in the great majority of instances, the patient sinks from the absorption of pus into the system, from serious affections of the stomach, of the bowels, of the brain, announced by the following symptoms: tongue covered with a yellow, greenish, brownish, or even black coating, moist at first, then dry; sordes about the teeth and gums; fetid breath; vomiting of bilious stuff; diarrhœa; involuntary passage of the urine and feces, which are black and offensive; pulse hard and frequent; slow and tardy replies to questions, vertigo, rambling, low delirium, subsultus tendinum and death.

3. Nothing is more common than to see œdema of the subcutaneous cellular tissue supervene on the last stage of simple erysipelas, or on the first period of phlegmonous erysipelas: it is even a constant occurrence in erysipelas of the eyelids and scrotum; but the title of *œdematous erysipelas* has been given more especially to that variety of the disease in which the swelling formed by the skin and subcutaneous cellular tissue is developed in a slow and gradual manner, and offers the resistance of œdema and of emphysema, instead of the tension of phlegmonous erysipelas. The skin, smooth and glistening, pressed on by the finger, retains the pit for a long time. It is uncommon to see any accidental blebs on the skin in this variety, and when they do occur, they are smaller and less elevated than in simple or phlegmonous erysipelas. They appear between the third and the fifth day, reckoning from the period of formation of the swelling, and, bursting, are succeeded by crusts of little extent or thickness.

The genital parts in the female, the scrotum in the male, the legs and swollen limbs of dropsical subjects, are the most common seats of œdematous erysipelas, which frequently occurs after the punctures made in the skin and loaded cellular membrane with a view to draw off water.

Of all the modes in which this affection terminates, gangrene, it may be conceived, is the most deplorable. This is indicated by violent pain, a red colour and shining appearance of the skin, which by and by becomes livid or leaden in its aspect.

229. The organization, or intimate structure of the skin and subcutaneous cellular membrane, modified in different regions of the body, renders these more or less liable to be affected by one or another of these varieties of erysipelas.

1. *Erysipelas of the face* is unquestionably the most frequent of all.

<sup>1</sup> Chevalier. Lect. on the General Struct. of the Hum. Body, p. 122.

It begins in the nose, the cheeks, the eyelids, or the lips, and extends with greater or less rapidity to the half and more commonly to the whole of the countenance. The lax tissue of the eyelids is swollen and œdematous; the eyes are closed and watery, the nose is enlarged, the nostrils are dry, the lips puffy, the ears red and shining; a copious secretion of saliva fills the mouth, which is opened with difficulty; sometimes the inflammation even extends to the nasal fossæ, the pharynx, and cavity of the tympanum; often, whilst the epidermis is detached in bran-like scales in some places, the phlogosis continues or appears in several others, especially on the nose, on the forehead and hairy scalp. Of all the varieties of erysipelas, that of the face is most subject to recede or disappear suddenly. This disagreeable termination is most commonly preceded or followed by affections of the brain or its membranes, announced by delirium, profound or lethargic sleep, subsultus tendinum, &c. In some cases the disappearance of the erysipelas has seemed to me to be subsequent to the affection of the brain. The most usual termination of erysipelas of the face is in resolution; it may be so ended on the one side, and on the other be terminated by the establishment of several suppurating points. Leveillé has seen erysipelas of the face complicated with pseudo-membranous inflammation of the larynx and trachea, the existence of which was not suspected till after death. Coryza, ophthalmia, external otitis and bronchitis are the most common complications of this variety.

2. *Erysipelas of the hairy scalp* has almost always the characters of phlegmonous erysipelas. Punctures and contusions, simple or complicated with wounds (*traumatic erysipelas*), and the incisions from operations performed on the scalp, are the most frequent causes of the disease. It usually first appears in the vicinity of the parts irritated, and sometimes on the opposite side, from the sixth to the tenth day after the solution of continuity in the integuments. At the beginning the pain of the head is dull rather than acute; the integuments are affected by an œdematous infiltration, and are soft and doughy. The skin, of a pale red colour, as if whitened over, pits under the pressure of the finger, preserves the print for a long time, and only very slowly regains its colour and former level. The slightest touch renews or increases the pain, which is always accompanied by febrile symptoms; the tension of the integuments of the occiput, and the swelling of the external ears, often make lying on the back or side almost impossible. If this disease be left to itself, shivering fits at irregular intervals supervene, and the patient falls into a state of coma. The inflamed skin becomes thin in parts, bursts, and gives vent to a quantity of pus and of shreds of cellular membrane, and of the occipito-frontal aponeurosis, become gangrenous. The scalp is almost never stricken with gangrene; being, according to the judicious remark of M. Dupuytren, furnished with blood-vessels which are independent of those that are distributed to the pericranial cellular substance. On the following days new openings are formed in the most depending parts near the centre of the erysipelas, and additional shreds of cellular membrane and of aponeurosis are detached; the discharge is abundant and offensive, the bones of the cranium are sometimes exposed, and if the disease be not checked in its progress, delirium, diarrhœa, and various other serious symptoms give warning of the approach of death.

3. *Erysipelas of the mamma* in women often presents all the characters of the phlegmonous form of the disease in the highest degree. The exposure of these organs to cold soon after delivery, the irritation arising from the sucking of the child, the first time of nursing, [and the excessive distension of the mammæ with milk, which is too often allowed to occur,] are the most frequent causes of the affection. It almost always ends in suppuration, and is usually accompanied by inflammation of the axillary glands.

4. *Erysipelas of the umbilical region* is principally observed among the new-born infants in foundling hospitals, lying-in hospitals, and similar institutions; it sometimes extends to the hypogastric region and to the genital organs. Gangrene is one of the common terminations of this affection, which, left to itself, is often fatal. Its occurrence is often ascribable to violence done to the umbilical cord, to bad food, and to the insalubrity of many of the establishments where the newly-born are collected. It is frequently complicated with peritoneal inflammation, and with umbilical phlebitis.

5. *Erysipelas of the groin* is occasionally symptomatic of the infiltra-

tion of fecal matters consequent on a perforation of the intestine towards the crural arch or inguinal canal. In this case the cellular tissue is crepitating and emphysematous.

6. *Erysipelas of the scrotum and of the prepuce* often ends in gangrene in elderly persons. The œdematous swelling of the prepuce is sometimes so great that the patient cannot void his urine; the scrotum, twice or three times its natural size, usually sphacelates at the points where it is in contact with the bed.

7. *Erysipelas of the limbs* is most usually confined to the forearm or to the leg. When it is set up in the neighbourhood of the articulations it is occasionally accompanied by inflammation of the synovial membranes. If the inflammation has extended deeply to the subcutaneous cellular tissue, the dimensions of the parts may be singularly changed: I have seen the arm acquire nearly the size of the thigh. The limbs are the most frequent seat of phlegmonous erysipelas: rest and proper position are two conditions indispensable to the obtainment of a speedy cure.

8. M. Renauldin gives a case of *general erysipelas* occurring in the person of a woman about fifty years of age. The whole skin of the trunk and of the limbs, slightly swollen, presented a very intense erysipelatous red blush; the face was the part least affected; the patient, who felt as if consumed by fire, was soon restored by the use of aperients, and tepid baths frequently repeated.

230. *Anatomical Observations.*—The most simple erysipelas attacks not only the vascular rete of the skin, but extends to the entire thickness of this membrane and to the cellular tissue lying beneath it.—*Phlegmonous erysipelas* does not differ in reality from *simple erysipelas*, save by the higher degree of inflammation that attends it. According to M. Ribes, in erysipelas the small veins of the integuments are the vessels principally affected, the ramuli of the arteries being less inflamed; the lymphatics appear to be implicated in a less degree than either the veins or arteries. The inflammatory blush is peculiarly remarkable on the internal coat of those small veins, the canals of which are filled with pus. On the termination of erysipelas in gangrene, the walls of these vessels are black, and tear with the greatest ease.

In my opinion, this condition of the arteries and veins is by no means constant; I have not found the slightest trace of inflammation of these small vessels in several cases of erysipelas I have examined. Besides, these remarks of M. Ribes could only apply to the subcutaneous veins; the vessels of the rete, and of the papillæ of the skin, are all too minute to permit of any demonstration of their inflamed state being made. But an alteration of the subcutaneous veins themselves is not a constant condition, and they may contain pus which has been absorbed. This was actually the case in one patient, the history of whose disease I shall detail particularly by and by. The skin of the face was pale everywhere, except on the eyelids, which preserved a slight degree of redness in the parts that had not been covered by phlyctenæ. The subcutaneous and intermuscular cellular tissue of the face was infiltrated by a yellowish sero-purulent fluid; small abscesses, containing laudable pus, existed in front of, and behind, the orbiculares palpebrarum muscles, among the cellular tissue of the orbit, and extended towards the temporal fossæ; the cellular substance of the scalp itself was also infiltrated. The parietes of the veins of the face and neck, although lying bathed in pus, showed no trace of inflammation. Many of these minute vessels contained purulent serum similar to that effused into the inflamed cellular membrane. The minute arteries were healthy. I have also found pus in the lymphatic vessels of a lower limb attacked with phlegmonous erysipelas, without any visible alteration of the parietes of the blood-vessels. In fine, I have met with true inflammation of the principal veins in limbs that were the seat of phlegmonous erysipelas or of simple phlegmon, and as a consequence of paronychia or of amputation. If I may be allowed to draw a conclusion from my own experience, I should say, that phlebitis complicates inflammation of the cellular tissue more frequently than that of the skin.

In phlegmonous and gangrenous erysipelas the morbid conditions of the skin and cellular substance are carried to a higher pitch; the pus is collected within one or more abscesses, or infiltrates the cellular membrane, which, in other places, appears loaded with sero-sanguinolent fluid. The skin, the subcutaneous cellular tissue, the

aponeuroses, the periosteum and the superficial bones themselves may perish. The bodies of those who sink under these diseases present several alterations that belong to pulmonary, cerebral, and gastrointestinal inflammations, such as small collections of pus in the lungs, in the liver, &c. Dr. Davy observed that the blood in erysipelas coagulated as speedily as in health, and that nevertheless it most commonly presented the buffy coat.

231. *Diagnosis.* The inflammation in measles is too general and too superficial to be confounded with erysipelas, moreover it is dotted, or disposed in small wavy or curved lines. Scarlatina, even when the eruption does not cover the whole of the body, differs from erysipelas in being contagious, and almost invariably preceded and accompanied by considerable soreness of throat; the strawberry red colour of scarlatina is, farther, very different from the deep red hue of erysipelas. In erythema, the inflammation often disposed in spots, is always more superficial and less extensive than in erysipelas, which, on the contrary, is spread over a large surface, often covered with phlyctenæ or vesicles, and always attended by the tumefaction of the subcutaneous cellular membrane. Numerous characters distinguish erysipelas from bullous diseases, particularly from pemphigus. It is, in conclusion, impossible to confound this exanthematous disease with phlegmon, furuncle, or anthrax; a position, which the descriptions of each of these complaints, if consulted, will make abundantly evident.

232. *Prognosis.* Simple erysipelas, without all complication, is a disease of little consequence, especially if the skin be inflamed over but a small extent of its surface. When the inflammation of the integuments has come on under the influence of causes that have acted primarily on the nervous system, or on the organs of digestion, or when (and this is the most common case) the cause is altogether unknown, the prognosis is less favourable. Phlegmonous and deep and extensive erysipelatous inflammations of the limbs are dangerous diseases; diffuse and wandering erysipelas, developed in the course of chronic disease of a febrile nature, is a symptom of the worst augury; phlegmonous erysipelas complicated with phlebitis or with the absorption into the circulation of purulent matter is almost always fatal.

On the other hand, peripneumonia, rheumatism and gout, have occasionally been seen replaced by an erysipelatous attack occurring shortly after their invasion. But it is in chronic inflammations of the skin that the appearance of an erysipelas has sometimes proved more especially advantageous.

The sudden and spontaneous disappearance of erysipelas is always an event of the most untoward kind; it is very frequently caused by the accidental evolution or progress of another disease more or less dangerous in its character.

233. *Treatment.* When slight erysipelas has been produced in a healthy individual by some evident cause, rest, the horizontal posture, especially if the disease have appeared in the lower limbs, lotions with tepid or cold water, or with any mucilaginous decoction, or gently anointing the part with lard, together with mild diluents internally, commonly suffice to put an end to the complaint, which, indeed, gets well almost as certainly if left to itself.

If the erysipelas is more intense and of greater extent, and if to the local inflammation there is superadded a burning and general heat of surface, dryness of the mouth and tongue, frequency, hardness and bounding of the pulse, &c., or if a plethoric state of the system at large exists, and seems an obstacle to the evolution and regular course of the disease, it is proper immediately to open a vein, and boldly to bathe the affected parts with cold mucilaginous lotions; in the course of the same day, or on the morrow, a local bleeding practiced at a certain distance from the limits of the inflammation, secures the good effects of the general depletion. These local bleedings ought to be repeated on the following days, if the blood have been very buffy, and if, when the disease is fully formed, the accompanying fever continue with the same degree of intensity as on the first appearance of the eruption. Whenever the erysipelas is complicated with phlebitis, the practice ought to be even more energetic.

It will be needless to recur to very active measures if the fever has declined either after the appearance of the eruption, or after the first bleeding, or in consequence of the disease, in its natural course, arriving at the period of decline. In the aged and cachectic, in

gangrenous erysipelas, or after the absorption of pus is deemed to have occurred, bleeding does mischief and ought to be shunned. If simple erysipelas has been preceded by symptoms of irritation in the stomach and bowels, it is well to apply leeches once or twice to the abdomen. Whenever the constitution of the patient has warranted the practice, or when the severity of the symptoms has required it, blood-letting has always appeared to me the surest means of combating erysipelatous inflammation occurring after one or several days of fever, and without any evident or appreciable cause—(*erysipelatous fever*). In erysipelas of the face, after the employment of blood-letting, the mustard foot-bath, blisters to the legs, and purgative glysters have often appeared to me useful and even necessary auxiliaries, and always to be recommended when there were threatenings of cerebral mischief.

The importance of blood-letting, then, in the treatment of simple erysipelas, extending to a large surface, or complicated with other diseases of greater or less gravity, is to me a demonstrated truth; but to be really serviceable, the quantity of blood withdrawn must be considerable, and must be taken away at the beginning of the disease, the symptoms of which it often moderates, without, however, cutting them short. When practised timidly, or too late in the disease, venesection neither prevents the ulterior progress of the inflammation of the skin and subjacent cellular membrane, nor the sympathetic mischief of greater or less amount that generally attends it.

When the digestive apparatus is free from inflammatory symptoms, which is by no means uncommon, another plan of treatment may be adopted; this consists in the administration of emetic doses of tartarized antimony. I have seen this mode succeed, whether the patients got rid or not of a considerable quantity of bile. Nevertheless, after a number of comparative experiments, I remain convinced that blood-letting is generally the most advantageous method of treatment, and that it is applicable in an infinitely greater number of cases than the tartar emetic plan. The often renewed idea that *emetics* in certain medical constitutions constantly cure erysipelas, then unsuccessfully attacked by other means, must by no means be received as a demonstrated truth. During one period (January, 1833), when this assertion as to the necessity of having recourse to tartar of antimony and ipecacuanha was reproduced at the royal Academy of Paris, several patients did very well in La Charité under the influence of the *expectant system*, after one or two venesections. Emetics, however, it may be conceived, are always necessary when erysipelas appears to be owing to the ingestion or to the presence of any acrid or poisonous substance in the stomach. Emetics and purgatives, so generally useful to the scrofulous, have been administered with advantage in erysipelas of the face, either as depletive agents or as derivatives; after a bleeding or two, combined with the foot-bath and purgative injections, they are often employed with greater success than when given alone. (a)

As to the *system of expectation*, it may be ventured on in cases of simple erysipelas, or of erysipelatous fever of little intensity; the cure is accomplished by the powers of nature; at one time, without any other phenomena than those that belong to the resolution of the inflammation, at another, after some form of *crisis*. In the *epidemic constitution* of 1721, during which erysipelas was very common at Turin, C. Richa informs us that the disease was often ended by slight diarrhœa, and occasionally by epistaxis. I have never observed such crises in my own practice; perhaps it is that I have not been careful enough in looking for them, or that I have interfered with their occurrence by my treatment.

Too unlimitedly adopted, the expectant method would certainly lead to the detraction of blood being delayed so long as to make it either less serviceable or altogether inadmissible; this is a difficulty which those practitioners who have assimilated erysipelas with the eruptive fevers, have not always succeeded in avoiding.

Frictions with mercurial ointment, and with lard or butter, though they seem occasionally beneficial in simple erysipelas, have, notwithstanding, no influence in preventing the phlegmonous form of the dis-

(a) In continuation of this antiphlogistic and revulsive treatment, colchicum, digitalis and antimony, with salines, may be advantageously had recourse to.

ease from generally running into suppuration. In cases of erysipelas of the face, I have often caused one side to be rubbed over with lard and the other with mercurial ointment; several times, too, one of these unguents was applied to one side of the face, whilst the disease was abandoned entirely to itself on the other; and I never perceived that the course of the disease was influenced by any of these proceedings. Such topical medicamentation has much less effect than those who have recommended it imagine. This is particularly evident in those cases of erysipelas that are preceded by fever of a day or two's continuance, and whose periods of increase, of status, and of decrease, are not interrupted by external remedies, which, in fact, do no more than diminish the heat, the dryness, and tension of the skin. With the same view it has long been the custom to dust limbs attacked with erysipelas with flour or powdered starch, to apply cataplasms with Goulard's wash, lotions containing alcohol or ether, &c.

Superficial cauterization with the nitrate of silver has been said quickly to stop the progress of erysipelas. The results of some trials I have made of the remedy are in opposition to this statement. (a)

Wandering erysipelas may be attempted to be fixed by the application of a blister to the place it occupies, or to that it has first possessed; internal inflammatory affections, should they occur, are to be met at the same time. Unfortunately, wandering and diffuse erysipelas often show themselves as ultimate phenomena, as the harbingers of inevitable death, in patients exhausted by long suffering. These erysipelatous affections are reflexions of a lesion deeper seated and more serious than a blister will reach or cure.

*Intermittent erysipelas* is a very rare disease; I have never seen it but in the face, and then it was preceded and accompanied by paroxysms of facial neuralgia. Whatever the type it affects, it commonly yields to the bark or sulphate of quinine, exhibited as in cases of periodic fever.

If called in time to see phlegmonous erysipelas of the limbs, after having bled once or oftener, according to the age and constitution of the patient, a number of leeches, in proportion to the extent and intensity of the inflammation, are to be applied; to encourage the bleeding from these the patient is to be plunged into a warm bath, and the parts affected are to be covered with soothing or narcotic cataplasms almost cold; the tepid bath should be repeated on the succeeding days, for it is a powerful means, and too much neglected in the beginning of the disorder. Unfortunately, when patients enter our hospitals, pus is usually already formed, and infiltrates the cellular membrane, or is collected within abscesses in different places. The skin is then hot, tense, shining, and of a deep-red colour. The limb has a pasty or doughy feel, which Boyer signalizes, with justice, as one of the signs of the termination of this disease in suppuration. It now becomes necessary to make a certain number of incisions immediately, which, by loosening the skin and the aponeurotic sheaths, are productive of great relief, give place to a large flow of blood and of sanies, and allow an exit to the pus infiltrated into the cellular substance, or collected into abscesses. In this way the formation of large and numerous abscesses, the occurrence of gangrene of the cellular membrane, and of extensive separations of the skin, are all prevented. The incisions are still useful though the pus is not yet collected into centres. This assertion, made by Mr. C. Hutchinson and disputed by Mr. Samuel Cooper, has become, to my mind, an incontestable truth, since I have witnessed the success with which M. Beauchêne, surgeon to the hôpital St. Antoine, pursues the practice. The number of these incisions ought to be relative to the intensity of the inflammation, and their depth must be calculated according to the swelling of the limb. When gangrene has already occurred in one or several points, it is proper to incise freely, and thus to fight against the inflammation wherever sphacelus has not yet taken possession of the parts. If, then, the advantages of incisions be incontestable, the practitioner must still be on his guard, and not permit any inconsiderate love of action to induce him to slash, and scar indelibly the whole of a limb attacked with phlegmonous erysipelas,

(a) Saturated alcoholic tincture of iodine, made of two scruples to an ounce of fluid, applied by means of a camel's-hair pencil over the whole erysipelatous surface and the surrounding sound skin, is an active and useful remedy. Velpeau recommends a solution of sulphate of iron; one ounce to the pint of water.

which repeated bleeding, the application of emollients, and the use of gentle purgatives would have cured, or at least made curable by a very small number of incisions. (a)

Several observations have been published in praise of blisters to the painful parts in the second stage of phlegmonous erysipelas. The surface of parts affected with traumatic erysipelas has also been slightly cauterized with advantage. The form of the iron employed for this purpose is of little consequence; it is only necessary that the instrument should be applied by a narrow surface to a great number of points of the integument attacked with the inflammation.—Whilst I acknowledge the good effects of these methods of treatment, comparative trials have led me to prefer another: general and local bleedings, and purgatives. These are more effectual in preventing the termination of phlegmonous erysipelas in suppuration and gangrene, whilst incisions give vent to pus infiltrated or collected into abscesses, and always produce a relaxation of parts that is favourable.

*Compression*, often useless and sometimes dangerous in the early treatment of phlegmonous erysipelas, is employed with advantage, towards the end of the disease, to diminish the œdematous and loaded state of a limb. It is the best means at our command in œdematous erysipelas. It has been successfully used in phlegmonous erysipelas complicated with phlebitis.

The precepts relative to phlegmonous erysipelas of the limbs are applicable to some cases of erysipelas of the hairy scalp, that resist bleeding, diluents, emollient applications, emetics and cathartics. An incision that implicates at once the skin, the cellular membrane and the occipito-frontal aponeurosis, eases the painful constriction caused by the distension and stretching of this fibrous membrane. It is usual to put a piece of lint between the edges of the incision in order to prevent their union, which should not be allowed to take place till the swelling of the scalp has completely subsided. Twenty-four hours after the incision, the patient is commonly relieved, and serious symptoms, such as delirium, and others proper to affections of the brain, generally yield within the same space of time.

Erysipelas, to conclude, is occasionally a salutary affection. It has been studied under this point of view by M. Sabatier: it is particularly in regard to some chronic diseases of the skin that erysipelas has brought about effects which perhaps would never have been determined by any other curative means. This beneficial influence

(a) Incisions, as practised by Dr. Hutchinson and Mr. Lawrence, are intended, not to evacuate matter already formed, but to prevent its formation. They constitute a mode of blood-letting, and give relief to a tense and over-distended skin. Mr. Lawrence, in place of several free incisions through the integument, down to the muscles, of about an inch and a half in length, and two or three inches apart, and varying in number from six to eighteen, recommends one long incision, through the whole extent of the affected part. The incisions will be of comparatively little use, unless they penetrate the fascia; and if the inflammation be suspected to have passed beneath the fascia, this should be divided.

Puncturing the part affected, a practice recently introduced by Sir. R. Dobson, of the Greenwich Hospital, is extolled by Mr. Liston and Dr. Bright, but is not thought well of by Mr. Travers. Mr. Nunnely declares that he has not seen a case in which puncturing did not seem to be advantageous, or where any unpleasant effects followed. "The comfort produced in a very short time is often perfectly surprising; the heat and burning pain become much less, the swelling is diminished, and the tendency to spread moderated. Another important advantage is, that it does not interfere with, nor prevent, any other application." (*A Treatise on the Nature, Causes and Treatment of Erysipelas*. Am. edit., p. 201.) Punctures serve to abstract blood, and, in this respect, are a substitute for leeches. The best method of making them is to hold a sharp lancet tightly between the finger and thumb, at such a distance from the point as we wish it to penetrate, thus making the finger and thumb the shoulders of the lancet blade. The depth will vary from one-fifth to two-fifths of an inch; the latter being that which is necessary only in the limbs where the swelling is considerable, when we wish to evacuate effused serum as well as blood. The flow of blood may be promoted by sponging the punctured surface with warm water.

may be exerted even when the disease is seated in a region remote, in a greater or less degree, from the affected parts. And this salutary action of erysipelas is not confined to mere vesicular, or papular, or pustular eruptions, in a word, to the morbid productions that exist on the surface only, or implicate but a certain thickness of the dermis; it may occasionally be seen inducing the resolution and suppuration of scrofulous tubercles, of indolent glandular swellings, modifying in a remarkable manner squamous eruptions of ancient date, causing the resolution and disappearance of syphilitic tubercles, accomplishing a prompt cicatrization of rebellious ulcers, favouring the re-union of the skin with the parts beneath in the fistulous passages about scrofulous sores, limiting lupus in its progress, &c. I shall have occasion to recur again to this influence: in such cases the erysipelas may be left to itself, provided its condition and progress be attentively watched.

The prophylactic treatment of erysipelas is a point worthy of consideration under certain circumstances. Its development may be prevented in females labouring under amenorrhœa, by the detraction of blood every month, at the periods of the menstrual flux. The same plan is to be pursued when the disease seems to occur in lieu of some habitual hemorrhage.

#### *Historical Notices and particular Cases of the Disease.*

234. There are numerous details of cases and several monographs that may be consulted with advantage on simple erysipelas,<sup>1</sup> on phlegmonous erysipelas,<sup>2</sup> on gangrenous erysipelas,<sup>3</sup> on general erysipelas,<sup>4</sup> on erysipelas of the whole of one side of the body,<sup>5</sup> of the face,<sup>6</sup> and of the navel, with inflammation of the umbilical vein;<sup>7</sup> on intermittent erysipelas,<sup>8</sup> on epidemic erysipelas;<sup>9</sup> on the contagion of erysipelas,<sup>10</sup> on the diagnosis of erysipelas and erythema;<sup>11</sup> on erysipelas that is salutary or critical,<sup>12</sup> on the retrocession of erysipelas,<sup>13</sup> on its complication with *phlebitis*,<sup>14</sup> and with cerebral affections.<sup>15</sup> Observations have also been published in favour of compression<sup>16</sup> in the treatment of the disease, of acupuncture,<sup>17</sup> of anointing with lard,<sup>18</sup> with oil of sweet almonds, with cream, and with mercurial ointment<sup>19</sup> whether the disease were simple or of the phlegmonous kind; in recommendation of *blisters*<sup>20</sup> in cases of erratic and of phlegmonous erysipelas; of cauterization with the *nitrate of silver*<sup>21</sup> or of the *actual cautery*<sup>22</sup> in

certain species of the disease. Several remarks on the effects of bleeding<sup>23</sup> ought likewise to be referred to, as also on emetics,<sup>24</sup> on the disadvantages of tincture of opium externally, &c.<sup>25</sup>

Under the general title of erysipelas,<sup>26</sup> Mr. Lawrence has included the ordinary or simple disease, and that in which the inflammation extends to the subcutaneous cellular tissue, the subcutaneous glands, the fibrous sheaths, and the synovial membranes. Rust<sup>27</sup> considers erysipelas rather as an *exanthematous fever* than as a simple inflammatory affection of the skin; and this idea would be correct, were all those diffuse forms of inflammation we see produced by local excitation to be thrown out of the class of erysipelas. P. C. Louis<sup>28</sup> has of late again called attention to the fact of fever frequently preceding the eruption; lastly, Rust has said that erysipelas is always accompanied by a certain accumulation of *animal electricity*, which is perceptible to the hand applied to the inflamed skin, a circumstance which I have endeavoured to verify, but in vain.

CASE IX. *Phlegmonous erysipelas of the face, more decided on the right than on the left side; arachnitis; tardy resort to blood-letting; death;—pus in the veins of the face.*—J. Col, 37 years of age, was admitted into La Pitié, the 14th of December, 1825. Five weeks previously, he had fallen into a ditch, where he remained three quarters of an hour, his legs and part of his body immersed in water. In consequence of this accident, he had pains in the legs, followed by infiltration of the lower limbs and abdomen. These dropsical symptoms were successfully treated by frictions with an ointment containing extract of aconite.

On the 3d of March, 1826, he complained of a sense of constriction about the epigastric region, and vomited without any assignable cause. March 25th.—Appearance of erysipelas of the face, occupying the lower part of the forehead, the eyelids and nose. The red colour of these parts, of no great depth except on the right upper eyelid, disappears on pressure; the swelling, which is little apparent on the cheeks, is very distinct on the forehead and nose, and extends to the temporal region on the right side; the eyelids are œdematous, especially those of the right eye, at the inner angle of which there exists a phlyctena; the inflamed parts are affected by a sharp and pungent heat, more violently felt in the eyelids than anywhere else. The abdomen is soft and tender to pressure, the tongue is dry and coated; the thirst very intense; anorexia, flitting colicky pains, constipation; free excretion of urine; cough without oppression; skin hot; pulse full and very quick; headache, disturbed sleep. 26th.—The forehead, the eyelids, the two cheeks, and the upper lip are red, swollen and shining; the parotid regions and the superior and lateral parts of the neck are also inflamed. The redness that extended over the right upper eyelid is replaced by a large bleb containing a seropurulent fluid; a small vesication of the same kind exists on the inner angle of the left eye. The nose and the whole of the right cheek are covered by yellowish incrustations, formed by the desiccation of a fluid that exudes from between the closed eyelids. The patient complains of darting pains through the whole extent of the parts affected. The febrile symptoms continue; crepitating rattle is heard at the lower part of the right lung; expectoration of mucous matter tinged with blood (*mucilaginous lemonade*). 27th.—Enormous swelling of the face, more especially of the right cheek, and of the parotid regions; livid red colour of the inflamed skin. (*Forty leeches behind the ears, sinapisms to the feet, emollient poultices to the face, mucilaginous lemonade.*) Delirium during the night; alvine evacuation (*mucilaginous lemonade*). 28th.—The swelling of the right parotid region has extended to the lateral parts of the neck and upper part of the thorax. The skin of the face, in some places shining and pallid, is of a livid hue on the cheeks, and upper parts of the eyelids; other symptoms much the same; delirium continues (*same prescription*). Worse and worse; collapse has succeeded the delirium; difficult deglutition. (*Two sinapisms to the thighs: wine and water.*) Death in the course

of the day. 30th.—*Examination of the body.* The face is pallid, except the eyelids, which are a little red in the parts that were not covered by phlyctenæ. The subcutaneous and intermuscular cellular tissue cut into, is found infiltrated with yellowish and puriform serum, and small collections of true pus exist before and behind the orbicularis palpebrarum muscles. This purulent infiltration is also found in the cavity of the orbit, and extends towards the temporal fossæ; on the left side, indeed, the cellular tissue of the scalp is itself full of matter. The tumour of the parotid region is formed by a copious effusion of the same purulent serum into the cellular substance surrounding the gland; the gland itself is not affected, but the cellular substance that enters into its composition, is loaded. A similar infiltration is observed to extend to the subcutaneous cellular tissue covering the pectoralis major of the right side. The parietes of the veins of the face and neck, although immersed among pus, present no traces of inflammation. Many of these small vessels contain purulent serum similar to that which is effused into the inflamed cellular substance. The minute arteries appear equally free from particular disease. The arachnoid membrane covering the superior hemispheres of the brain is thickened and opaque; the corresponding sub-arachnoid cellular substance is loaded with serum. The dura mater on several parts of the base of the skull is red, as is also the superposed arachnoid. The third ventricle of the brain contains a large quantity of serum; the lateral ventricles are less distended. The consistency of the brain and cerebellum is natural. *Thorax and abdomen.* Partial but old adhesions of the pericardium to the heart; heart somewhat larger than natural; adhesions between the lungs and pleura; lungs crepitating; redness of some of the ramifications of the bronchia; redness of the mucous membrane of the œsophagus; blackish and greenish hue of the great end of the stomach, and of some parts of the small intestines, which appear to be the result of inflammation and putrefaction; the other organs of the abdomen present no particular appearance of alteration.

## RUBEOLA.—MEASLES.

Vocab. *Rubeola, Morbilli, Blactiæ, Measles.*

235. Rubeola, or measles, is an exanthematous and contagious inflammation, preceded by chills and shivering fits, accompanied by watering of the eyes, sneezing, and hard dry cough, and characterized externally by an eruption of small red spots of the size of flea-bites, prominent at the points where the cutaneous follicles surpass the general level, separated by irregular narrow interstices, in which the skin seems healthy, forming afterwards, by their conjunction, small crescent-shaped patches, which decline towards the seventh or eighth day from the date of the attack, and are commonly followed by a furfuraceous or bran-like desquamation.

236. Measles presents several varieties: 1. *Rubeola vulgaris*; 2. *Rub. sine catarrho*, sive *spuria*; 3. *Rub. nigra*; 4. *Febris morbillosa*; 5. *Rub. anomala*; *Rub. maligna*.

237. *Rubeola vulgaris*, (*morbilli benigni, vulgares*). Common measles presents three *stadia*.

1st Stadium.—(*Stadium contagii*, Rosen.—*Apparatus efflorescentiæ*, Morton.)—Common measles begins with alternate chills and flushes, general uneasiness, lassitude of the limbs, and feeling of depression, pain and weight over the eyes and in the forehead, accompanied by drowsiness and a disposition to sleep. The pulse soon shows acceleration, the skin becomes hot, the surface of the tongue is whitened, its tip and edges are of a bright scarlet colour; thirst is complained of, the stomach is irritable, and there is nausea and sometimes vomiting; the epigastrium at times is painful. On the *second day* of the attack, all these symptoms are aggravated; the eyes grow red and weep incessantly, the sneezing is more frequent, the patient complains of itching in the nasal fossæ, and there is a secretion of limpid mucus from the nostrils; he is oppressed, and feels a load about the epigastric region. The throat is slightly affected; cough, of variable degrees of violence, commences, and, in very young subjects, drowsiness, and, occasionally, slight and passing convulsive fits are added to these phenomena. On the *third day*, the severity of the symptoms

still goes on increasing; the eyes become more sensitive and inflamed than ever, the eyelids and their edges appear a little swollen; there are dry and frequent cough, hoarseness, dyspnœa, a sense of constriction, sometimes of anxiety, in the chest, with drowsiness or delirium; a fit of sickness or of diarrhœa in children cutting their teeth, or a copious sweat, of a peculiar sweetish-sour smell, precedes the appearance of the eruption, which commonly shows itself on the *fourth day* from the invasion of the symptoms of indisposition, which may correspond with the tenth, eleventh, twelfth, thirteenth or fourteenth day of the infection.

2d Stadium.—(*Status morbi*, Morton.—*Stadium eruptionis*.)—Small red spots distinct from each other, almost circular, but little prominent, and very similar, in all respects, to flea-bites, appear first on the forehead, chin, nose, cheeks, and around the mouth, and spread successively, during the same day or on the morrow, over the neck, the breast and the limbs. This eruption is almost always accompanied by itchiness and great heat of skin. The greater number of these small circular spots are, by and by, replaced by others of a larger size, which are sometimes disposed in clusters, (*Rub. corymbosa*), not exactly defined, but tending to the form of a crescent or semicircle (*racematim coalescunt*, Sydenh.). These two kinds of spots are blended and lost in the neighbouring skin; under the finger they convey no impression of a rough, uneven, or prominent surface. The semicircular patches are formed by the junction of the small rounded spots which have already been mentioned, and the little points that compose them may often be counted upon the circles which are separated from each other by interstices or spaces where the skin preserves its natural colour. The colour of these spots is less vivid than that which the integuments present in scarlet fever. It is enough to stretch the skin a little, to make the redness disappear. Small rosy-coloured papular elevations are sometimes observed on the surface of the skin, which, when they are very numerous, give the eruption a peculiar appearance. On the face, the red colour of the patches is at its height about the *fifth day*; on the sixth day, the patches there begin to decline, at the same time that those on other parts of the body become deeper-coloured and more abundant.

On the fourth day of the invasion small spots of a dull red colour are also sometimes to be perceived on the uvula and velum palati, similar to those which are seen on the skin. On the fifth day they become confluent. This slight inflammation causes the patient to complain of dryness and roughness of the throat, and increases the hoarseness that had come on earlier in the disease.

When the eruption is completed, the frequency of pulse, the heat, the thirst, the redness of the eyes, the coryza, the soreness of the throat, &c., decline considerably in intensity, and sometimes even disappear entirely. The sense of pectoral oppression and the cough alone continue in some individuals; the nausea and vomiting have ceased from the fourth day, and the sense of heat, oppression, and restlessness generally vanish about the sixth.

3d Stadium.—(*Crisis; declinatio vel desquamatio*.)—On the fourth day of the eruption, which corresponds with the seventh or eighth of the invasion, the patches of measles begin to die off in the order of their appearance, and then assume a pale yellowish colour. These yellowish spots are more permanent than the redness to which they have succeeded; they cannot be made to disappear by stretching the skin. The epidermis soon begins to be detached in a very minute furfuraceous scurf from those parts which the redness has left; the skin, now become dry and sometimes rough, is affected with a troublesome pruritus that lasts till the tenth or twelfth day. Occasionally, however, the desquamation either does not occur, or is insensible; this, at least, is the case on certain regions of the body, or on several patches of the eruption. At this period the symptoms of inflammation of the air-passages decline gradually; the expectoration, which is always wanting in infants at the breast, affects adults slightly in this variety of the disease; in less simple cases, however, the cough and expectoration continue for some time during the state of convalescence.

238. *Rubeola sine catarrho*.—During the epidemic prevalence of measles, Willan observed that a certain number of patients were covered with an eruption, whose external appearance and course were the same as those of common measles, from which, neverthe-

less, it differed by being unaccompanied with fever, catarrh, coryza, &c. He adds that an interval of several months, or even of two years elapsed between the occurrence of this eruption and the development of common measles, which, however, most commonly happened three or four days after the non-febrile eruption. I have had several opportunities of verifying this fact; and I have seen circumstances attending them which confirmed more decidedly the measly nature of these eruptions. I have, for instance, seen all the children of one family, playing and even sleeping in the same room, attacked with well-marked catarrhal measles, except one, who only exhibited the symptoms of the 1st stadium of the disease, and those of the eruption, without the bronchial affection. Are these cases of measles without catarrh, considering them as effects of an epidemic cause, analogous to the cases of varicella observed during the epidemic prevalence of small-pox? It is difficult, otherwise than by their cause, to distinguish them from certain forms of roseola; to distinguish between them is impossible when they are sporadic. (Vide sub *Roseola*.)

239. Under the title of *rubeola nigra* Willan has signalized an appearance but rarely met with, inasmuch as the eruption, towards the seventh or eighth day, reckoning from the invasion, becomes completely livid, with the addition of a shade of yellow. This variety of the disease has principally been observed to occur in individuals of weakly constitution. Dr. A. T. Thomson, in the case of a child eight years of age, attacked with this variety, observed that the epidermis was raised like a moist spider's web, when the wrist was pressed in feeling the pulse. I have seen various examples of these livid measles in children, labouring under tubercles of the lungs and chronic cæco-colitis, and who were exhausted by diarrhœa and hectic fever. In these cases the greater number of the patches of measles do not disappear under the pressure of the finger; and when the life of the children labouring under them is protracted for a few days beyond the ordinary duration of measles, the skin presents morbillous spots which differed from those of purpura simplex in their form and distribution, but which, like these last, exhibited shades of brown, and of yellowish or dirty gray, according to the degree of re-absorption that had taken place in the blood effused into the skin. I shall give a case particularly adapted to make the reader acquainted with another variety of black or hemorrhagic measles, in which the greater number of the spots were of a vinous red colour, and did not disappear on pressure. This variety does not appear, like the preceding, to be connected with any weakening of the constitution from previous illness; I have met with it in strong and well-constituted individuals. On this occasion I shall call attention to the fact, that in common measles, if the surface of the body be examined with due care and attention, a certain number of patches will almost always be discovered of a deeper red colour than the rest, not disappearing entirely on the pressure of the finger, and subsequently becoming of a yellowish colour and vanishing more slowly than the others during convalescence.

240. *Measles without eruption.* (*Febris morbillosa*.) This variety, not less remarkable than those that precede, has been observed during the epidemic prevalence of measles. Sydenham mentions anomalous measles in 1674, and a *febris morbillosa* that prevailed at the same time, which was characterized externally by an eruption of patches upon the neck and shoulders resembling those of measles, from which, however, they differed in being confined to the places mentioned, and not spreading over the whole body. Gregory goes further when he states that he has seen measles without any eruption whatever. M. Guersent has observed some individuals in families where measles prevailed, exhibiting all the other symptoms of the disease except the eruption. I have myself several times seen cases of measles in which the eruption was incomplete, and which might have been referred to the morbillary fever of Sydenham, but I have never met with any instances like those mentioned by De Haen, Gregory and M. Guersent, although my attention has been turned to this point these some years past.

Influenza and several varieties of bronchial affection sometimes prevail at the same time as measles.

241. *Anomalous and complicated measles (rubeola anomala).* In children who have fine and delicate skins, measles sometimes appears

partially on the third day; in others differently constituted again, it does not show itself before the fifth or sixth day; its progress is often checked or altogether stopped by exposure to cold, or the unseasonable use of purgatives. A little girl attacked with measles and complaining of pruritus in the nostrils, was believed to have worms; after the exhibition of a purge the eruption disappeared suddenly, and could not be recalled. Such a recession of the eruption is often accompanied by pains of the bowels, by diarrhœa, difficulty of breathing, delirium, convulsions, &c.; in other circumstances the eruption appears on the arms after having been observed on the face; or, otherwise, it is not propagated to the limbs, which do not exhibit a single patch over their entire extent.

242. In new-born babes papular eruptions resembling strophulus, and in patients of different ages, vesicles analogous to those of miliaria, blebs of pemphigus, petechiæ, accidental pustules, pustules of the natural or inoculated small-pox, epistaxis, acute inflammations of the eyelids, affections of the brain, different inflammatory affections of various degrees of importance, such as croup, bronchitis, pneumonia, muco-enteritis, &c., by being associated with the eruption of measles, give a vast variety of symptomatic characters to the disease, the peculiar form of each of which must be sought for and studied in particular cases.

When diarrhœa occurs in the course of measles, it is sometimes a serious symptom, especially if it be accompanied by restlessness and frequent cough. Diarrhœa occurring during convalescence may prove, according to its nature, duration and effects, either dangerous or critical and salutary.

Convulsions frequently enough accompany the disease when it happens during dentition, and very often terminate fatally.

243. Measles may sometimes exert a beneficial influence on chronic inflammations of the skin. I had a young woman under my care at the hôpital St. Antoine, on account of chronic eczema of the face, of the hairy scalp and ears, who got well under a violent attack of measles. On the contrary, however, M. Alibert has given two cases of children labouring under impetiginous eczema of the scalp (*achor mucifluus*), who, having contracted the measles, were suddenly relieved of their aches, but not long after sunk and died.

In some cases measles has appeared to cause the development of pulmonary tubercles; often, too, it seems to hasten their progress.<sup>1</sup> When measles is contracted at the same time as small-pox, the measles is commonly first developed, and then causes a suspension of the progress of the variolous eruption. Viesseux relates an instance to the contrary.

244. *Consecutive diseases.* (*Morbi secundarii; dregs.*)—During convalescence from measles, we frequently observe, on the back, groins and lower limbs, pustules similar to those of ecthyma, or an eruption of the same form, but of smaller size, scattered over the feet, legs, thighs and scrotum. In other cases, we meet with chronic inflammation of the eyelids, of their margins, or of the conjunctiva, with vesicular eruptions upon the external ear, and chronic enlargements of the subcutaneous lymphatic glands; lastly, with bronchial affections, obstinate cough, analogous to whooping-cough; inflammatory affections of the mucous membrane of the cæcum and colon, of the lungs, pleura, &c., which are all frequently made more obstinate by their special cause than other inflammatory affections having the same seat and the same extent, but which are induced under other influences. Measles is a disease that is often followed by phthisis, as Fred. Hoffmann long ago remarked. (a)

245. *Anatomical observations.* Vogel regarded the eruption of measles as situated in the epidermis. More accurate investigation has showed that measles especially affects the reticular tissue of the skin and the mucous membrane of the air-passages, as these parts are found injected in the bodies of those who have died of this disease. The anatomical characters of measly inflammation, the redness of the

(a) I have seen tubercular phthisis succeed immediately to measles. The hectic fever seemed to be but a continuation of the rubeolous one, and terminated fatally in a short period—seven weeks from the first attack. Otitis is a common sequela of measles.

<sup>1</sup> Andral. Clinique Medicale Ire., ed. iii. p. 49.

bronchial and intestinal lining membrane, and the secretions poured out from these, are not apparently different from those which are observed after other inflammatory affections not of a specific nature. Laennec conceives that the suffocating orthopnoea, which sometimes carries off children after measles, is caused by true idiopathic oedema of the lungs. I have seen this difficulty of breathing produced by intense bronchitis, with a fatal *pseudo-membranous exudation*. In anomalous and complicated cases of measles, lesions of various kinds, according to the parts affected, are discovered; it sometimes happens, also, that the death of the patient cannot be explained by any alteration of the solids detected in the examination of the dead body. (a)

246. *Causes.* Sporadic or epidemic measles is produced by a specific cause, the nature of which is unknown, and which, in general, acts no oftener than once on the same individual. The disease is readily transmitted among those who live in the same house; yet, so necessary is a certain disposition to contract the infection, that we see individuals who resist the influence of a first epidemic, attacked during a second. Tozetti, Schack, De Haen and Meza, inform us that they have seen measles affecting the same individual again and again, whilst Rosen assures us that, during the course of a practice of forty years, he had not known a single instance of the kind. Bateman admits the possibility of such an occurrence, from the statement of Dr. Baillie. In a letter to G. L. Targioni, Genovesi<sup>1</sup> states that, during the continuance of the universally prevalent measles of 1787, he had examined forty-six persons, children as well as adults, affected with measles, although they had already gone through the disease some years before. In the epidemic measles that reigned at Vire, in 1777, Duboscq had occasion to treat several children whom he had attended in 1773. Since the publication of the first edition of the present work, I have seen three very remarkable instances of the recurrence of measles. One occurred in the person of a little girl, seven years of age, who, three months after a well-defined and severe attack of measles, complicated with pneumonia, was again seized with the disease, ushered in by catarrh, dry cough, and affection of the nose, and followed by obstinate inflammation of the eyes.

Some individuals may have frequent communication with patients labouring under measles, without taking the disease. A young married woman having contracted measles, communicated it to her eldest daughter, three weeks afterwards, whilst a younger child, who was night and day beside her mother and sister, escaped entirely. Nevertheless, the number of those who appear unapt to contract measles, is comparatively smaller than that of individuals unvaccinated, who continue to resist the contagion of small-pox. Bursarius goes the length of saying that there is probably hardly an individual in existence, who is at all times unsusceptible of the infection. Measles attacks every age, and occurs in every climate. P. M. d'Anghiera says that, previously to the year 1518, when it was imported, the disease was unknown in the New World.<sup>2</sup>

The disease is usually observed in young children; adults sometimes suffer from it, elderly persons very rarely. Vogel and others assure us that infants at their birth have presented traces of measles. It more frequently attacks children after than before teething. Dr. Barron has observed that angina and cerebral affections were the most common complications of measles in infants at the breast. The disease is communicated by contact or by infection; it may also be produced by the inoculation of the blood of those labouring under it, as the experiments of Dr. F. Home, verified by those of Speranza during the epidemic prevalence of measles at Milan, in 1822, have proved. Speranza at first inoculated six lads, in one of the work-houses, in whom the disease was soon developed, and ran its course regularly and mildly. The same experiment has been repeated by other practitioners, as well as by Speranza himself, under different cir-

cumstances. A very slight incision or scratch is made with the point of a lancet over one of the largest and most inflamed of the measly patches, so as to draw a little blood. A few punctures are made in the arm of the party to be inoculated, with a lancet poisoned with this blood, and the part is covered with a bandage. The effects of this inoculation are generally manifested a few days afterwards. Dr. Alex. Monro<sup>3</sup> and Locke<sup>4</sup> communicated measles by inoculating with the tears and saliva of persons labouring under the disease. Dewees informs us, on the authority of Dr. Chapman, that attempts of the same kind were in vain made at the dispensary of Philadelphia, in 1801, although the blood, the tears, the nasal and bronchial mucus, and the exfoliated lamellæ of the epidermis were successively employed in the trials. I have not myself repeated these experiments.

247. Measles most commonly prevails as an epidemic at the end of winter and beginning of spring. That observed in 1671, in London, by Sydenham, and that of Upsal, in 1752, described by Rosen, were *benign*; but the disease, in an *anomalous* and *malignant* form, prevailed at London in 1674; occurring at Plymouth in 1741, and mentioned by Huxham. It was often complicated with *pneumonia*. In the Foundling Hospital, in 1763 and 1768, Watson twice saw a *putrid* form of measles prevailing. Very severe forms of measles, complicated with miliary eruptions, were observed at Vire, in 1772 and 1773, and are described by Polinière and Le Pecq de la Cloture. The measles which prevailed at Paris in the year vi—(1797), were greatly complicated by *abdominal affections*; in the year vii—(1798), they were sometimes associated with scarlatina. During an epidemic measles, observed at the end of 1800 and beginning of 1801, by Consbruch,<sup>5</sup> several children were attacked with *morbillary fever without eruption*. They suffered under a violent fever, with all the catarrhal symptoms which accompany measles, and then there came out either an eruption that was scarcely distinguishable, and disappeared rapidly, or there followed a copious sweat, or a diarrhoea, or an unusual excretion of urine. Every one of these evacuations had something peculiar about it; they were all evidently, says the narrator, *morbillary fevers*, which had been preceded by influenza and hooping-cough.

By contrasting the accounts of these and a great many other epidemic measles that have been left us, we perceive that the majority of them have presented a character either of *mildness* or *malignity*, and that almost all, without exception, were preceded by catarrhal affections, by influenzas, hooping-coughs, &c.; diseases of old pointed out as preludes to *morbillary constitutions*. These have farther, sometimes, been observed to follow epidemic small-pox. During the present year, 1833, we have had occasion to remark this succession, referred to particularly by Störck and De Haen. I have seen many children who, after having had a dry barking cough (*toux ferine*) for a fortnight, have then been attacked with measles. (a)

248. *Diagnosis.*—During the period of *contagion* or of *efflorescence*, the existence of measles may be presumed if the fever be accompanied by redness of the eyes, a copious flow of tears, and of thin mucus from the nostrils, with sneezing, pain and heat of throat, and dry and distressing cough; if measles prevails at the time, and the patient have not yet had the disease; if other members of the family are affected in the same way, or if any communication has been held with infected individuals. At the *beginning of the eruption*, the diagnosis is not yet quite certain; the small red spots by which the disease is announced bear a strong resemblance, whilst they are yet isolated, to those of small-pox; but they are not long in being gathered into circular bunches or groups, (*in racemos collecta*, Forestus;) if they be generally a little raised, and, as it were, papular on the face and

(a) The chief deviation from health in the state of the blood, in measles, as noticed by M. Andral (*Hématologie Pathologique*), is in the increase of red globules. There is but little change in the proportion of the fibrin.

<sup>5</sup> Vermischte practische Bemerkungen. (Hufeland's Journal, B. xiii. St. 3. S. 31.)

(a) Measles sometimes assumes an epidemic character at the same time as small-pox; in its increase and decline corresponding with the like progress of the latter disease. This was eminently the case in the years 1823 and 1824, in Philadelphia, as recorded in the papers on "Small Pox and Varioloid," by Drs. Mitchell and Bell, in *North Am. Med. and Surg. Journ.*, July and Oct., 1826.

forehead, they present the appearance of true *stains* on the breast and limbs, very different from the *elevations* of variola, which, at a later period, become true pustules. Measles presents characters which distinguish it completely from the other exanthemata, and particularly from scarlet fever. In the latter disease, the redness is evenly spread and continuous, the eruption is not grouped or clustered, with interspaces of sound skin, or its patches, at least, are much larger than those of measles, and have an appearance more analogous to what is observed on erysipelatous surfaces. When the redness and tumefaction of the cheeks are very great in measles, the particular characters of the morbillary exanthema, very evident on other parts of the body, may be there obscured. Lastly, in the greater number of cases of measles, there is a hard dry cough, (*toux ferine*;) and sometimes expectoration of a particular kind; whilst, in scarlatina, the tongue, the mouth, and the throat are commonly of a vivid red, without cough or expectoration. In scarlatina, the cuticle is thrown off in large flakes, especially over the palms of the hands; whilst, in measles, it is detached in scales or scurf. Measles differs from *summer roseola* less in the form and appearance of the eruption than in being so uniformly attended by weeping of the eyes, cough, alteration of the voice, &c. It is more difficult to distinguish measles, and especially the variety *without cough*, from those eruptions which Willan has united under the head of *roseola*. (See *Roseola*.)

The occurrence of the eruption, in common measles, will always prevent the disease from being confounded with ordinary pulmonary catarrh, or with influenza. At the close, morbillary catarrh sometimes gives occasion to a particular kind of expectoration, which has attracted the attention of M. Lerminier and of M. Andral. At first mucilaginous, clear and limpid, at the end of three or four days the expectoration becomes thick, rounded into pellets, smooth on the surface, of a greenish-yellow colour, remaining perfectly distinct from each other, and swimming in a large quantity of ropy and transparent mucus, similar to the matter coughed up by some phthisical patients. By and by, this form of expectoration is exchanged for another, which adheres to the bottom of the vessel, and seems composed of a grayish homogeneous mucus, mixed with air and saliva, and very similar to the ordinary matter expectorated during chronic catarrhal affections. In young people, the expectoration is wanting, or not at all abundant; and many cases of measles occur in older subjects, without being attended with expectoration.

In reference to those *morbillary catarrhs* (*measles without eruption*), which have been observed to occur during epidemic measles, and are owing to the specific cause of this disease, they present several characters, even during life, adequate to distinguish them from common inflammatory affections of the air-passages; the cough is sonorous, and has a peculiar harsh and hoarse quality; the expectoration is occasionally in pellets, (*nummulaires*, *coined*;) and the continuance of this catarrhal affection is analogous to that of common measles. I know not whether a person labouring under morbillary catarrh has the power of communicating common measles, accompanied with an eruption, or not; a circumstance which, were such a power possessed, would constitute an important diagnostic feature in this form of the disease.

In measles it is always well, by a careful examination of the organs subservient to digestion and respiration, to ascertain the extent and intensity of the internal inflammations which accompany the progress of the disease, and particularly to watch those of the gastro-pulmonary mucous membrane.

*Morbillary ophthalmia* commonly appears before the development of the eruption. It is always attended by a great flow of the fluids of the eye, and follows the course of the principal affection. In weakly and scrofulous children, this adjunct does not often appear till towards the decline of the exanthema. As to any ophthalmic affection that may come on later, it must be held owing rather to imprudence in diet, exposure to cold, &c., than to the special cause of measles.

249. *Prognosis*.—Epidemic measles, so generally a mild complaint in temperate seasons and climates, is often a much more destructive disease in inclement seasons, and in countries that are either very hot or very cold. Yet the fact is certain that the same town, or the same province, may be visited at different times, by measles as an

epidemic, of a very benign, or of a very destructive character.—The epidemic of 1671, observed at London by Sydenham, was benign; that of 1674, on the contrary, was remarkable for the frequency with which the disease was complicated with peripneumonia.

Mild and regular measles ought to give us no solicitude, especially when the symptoms decline after the eruption.

Regularity in the course of the disease, little severity in the symptoms of gastric or pulmonic inflammation, and in the fever, general moisture of the skin after the appearance of the eruption, an equal distribution of the patches over the face, the trunk and the limbs, are all favourable symptoms. Tissot says that considerable evacuations by sweating, by the urinary organs, and bowels, in the course of the disease, are of good augury; I have witnessed many very speedy recoveries without any of these evacuations taking place, and I have generally seen diarrhoea more pernicious than salutary.

The *precursors* of the eruption are generally severest in young children, especially during dentition. The disease is most dangerous in pregnant women, and in women newly delivered, in individuals who have long laboured under a chronic affection of some important viscus, and especially in those who are affected with pulmonary tubercles. Still the severity of the eruption is, in general, subordinate to the gravity of the internal lesions that accompany or that succeed it. The eruption of the measles before the third day, its tardy, irregular, or incomplete appearance, its sudden or rapid disappearance, a leaden hue of the patches, the evolution of petechiæ with much dyspnoea, are serious symptoms. They often proclaim the existence of pneumonia, which is at once detected by auscultation and percussion of the thorax. The livid or blackish tint of the spots does not make the prognosis more unfavourable in certain cases of *hemorrhagic* measles, which in other particulars exhibit the usual symptoms of the common disease.

The disappearance of the eruption from exposure to cold, may be followed by serious metastases, and sometimes even by death.

The co-existence of several kinds of inflammation of the skin, and particularly of that of variola, renders the prognosis more doubtful if the general disturbance of the system is increased. Affections of the brain and of its membranes, croup, laryngeal angina, and pseudo-membranous bronchitis may rapidly bring about a fatal termination, which, in the majority of cases, then happens towards the eighth or ninth day from the invasion, or else at a much later period, in consequence of the progress of *secondary* diseases.

250. *Treatment*.—When the inflammation of the air-passages, that accompanies the eruption of measles, is of no great intensity, and the disease advances mildly and regularly in its course, the treatment is exceedingly simple. The patient must be covered so as to defend him from cold and sudden changes of temperature, but not so as to make him feel loaded and oppressed with heat; he must be kept upon low diet, and directed to make free use of any mild or slightly diaphoretic tepid drink; to allay the cough and irritation about the throat, he may have some sweet mucilaginous mixture to take by spoonfuls, and inhale the vapour of warm water at intervals, which will, probably, alleviate both the coryza and soreness of throat; the eyes must also be defended from too great a glare of light. Such are the means which it is generally proper to employ in the treatment of simple or common measles. During the whole course of the disease, children, who are apt to toss off the bed-clothes, and thus become exposed to the cold, ought to be sedulously watched both night and day.

The treatment of measles without catarrh, may be all comprised within an unstimulating plan of diet, and the use of diluents.

The inflammatory affections that precede, accompany, or follow measles, in proportion as they are severe, require a greater degree of care and attention on the part of the practitioner. The application of leeches to the epigastric region, when the intestinal canal is the seat of the adventitious malady, and to the fore part of the neck when laryngitis is threatened, with one or two bleedings from the arm, when the lungs are invaded, will commonly give a most favourable turn to the symptoms, secure the development of the eruption when it has not yet appeared, regulate it when it has come out imperfectly, and bring about its restoration when it has vanished suddenly.

Bleeding may be employed in every period of the disease, should any complication indicate the measure as necessary; it is most gene-

rally enforced previously to the breaking out of the disease. The appearance of the menstrual flux, or its existence, if no abatement of the symptoms have followed, presents no obstacle to the detraction of blood. In very young subjects, the application of leeches to the upper part of the chest is generally preferable to bleeding from a vein, and they ought to be repeated in numbers and frequency according to the urgency of the symptoms; in children under five years of age, general blood-letting is not indicated, except in the event of threatened and sudden suffocation, or of very severe pneumonia.

The leech-bites sometimes flow so freely when the breathing is oppressed, that they require to be watched; attention should at the same time be paid to keeping the surface of the body from all impression of cold, of which there is always great risk whilst the cloths or poultices are changed, should these have been employed to encourage the bleeding; or otherwise, when the patient is uncovered for the purpose of having the flow of blood checked by the application of starch, or lint, or, should these fail, of the nitrate of silver in substance.

The oppression, anxiety, palpitations, and general restlessness, observed on the third, fourth, or fifth day of the disease, do not require general or even local blood-letting for their relief, unless these symptoms be unquestionably due to acute laryngitis, intense pneumonia, or very extensive bronchial affection. In any other case bleeding might be hurtful by interrupting the natural course of the disease, rendering the eruption less abundant, and the crisis less decided. When the detraction of blood is abstained from, the oppression and anxiety, and difficulty of breathing, subside after the appearance of the eruption. I ought to add, that the general or local bleedings practised by Rhazes *ad diliquium*, and by Mead and Selle in greater moderation, have not so marked and beneficial an effect on the inflammatory affections of the air-passages depending on measles, as on those produced by exposure to cold, or any other cause not of a specific nature.

Should the eruption happen to disappear suddenly, it is well to try to ascertain whether this event be owing to the accession or increase of any internal inflammation, or to convulsions, or, finally, be not the effect of exposure to cold. In the former case, the complication must be met directly and in the usual way; in the latter, the patient must be plunged into a warm bath, or have a succession of hot cloths applied to his chest and extremities, with a view to excite perspiration and restore the eruption: if the case seem very serious, sinapisms may even be applied over the same parts. Blisters are more particularly useful in cases of measles complicated with pleurisy or pneumonia, after one or two bleedings have been practised. (a)

When *convulsions* supervene in children attacked with measles during teething, leeches must be applied under the ears, a blister be put upon the scalp or nape of the neck, and small doses of calomel given internally, at the same time that means are used to recall the eruption, should this have receded. The reappearance of the exanthema in such cases ought not always to induce us to prognosticate favourably of the issue; I have seen the convulsive fits continue in spite of this event, and children die a few hours after its occurrence.

When there is *diarrhœa*, it should be treated by soothing poultices to the abdomen, by mucilaginous injections, and by opiates in small doses. The practitioner must be on his guard not to confound simple serous diarrhœa with those slimy and bloody evacuations that indicate inflammation of the mucous membrane of the cæcum and colon, and require the application of leeches to the fundament and along the course of the large intestines.

In *laryngeal and tracheitic inflammation*, accompanied with frequent distressing cough having a croupy sound, it is necessary to abstract blood from the fore part of the neck, and then to administer emetics of tartrate of antimony or of ipecacuanha; the effort of vomiting is almost always followed by beneficial diaphoresis; in merely purgative doses, these medicines prove much less useful.

(a) In cases in which the eruption recedes, and there are accompanying marks of pulmonary or bronchial phlogosis, blood-letting and the cooling regimen will be the most appropriate treatment. I have known free drinking of cold water bring out the retrocedent eruption, and even cause mild diaphoresis.

*Inflammation of the throat* is allayed by soothing drinks and gargles, and by the foot-bath; should slight epistaxis supervene, it ought not to be checked.

The *ophthalmia of measles*, if slight, may be left to itself; if more severe, it should be treated by leeches and soothing fomentations; a blister to the nape of the neck and purgative medicines are required when the affection remains during convalescence: it is, in general, a disease of little moment. (a)

The expectant or moderate antiphlogistic plan of treatment is available in the variety of *hæmorrhagic measles*, which, in its symptoms, assimilates itself with common measles. When, on the contrary, the eruption is very pale and has a livid tinge, when the pulse is small, quick, and the skin is scarcely or not at all hot, and these phenomena appear linked with a cachectic state of constitution, weak wine and water, decoction of bark, camphor and ether, sometimes prove means of establishing a beneficial reaction; a phenomenon which it must also be a main object to induce whenever the regular course of measles appears to have been interfered with by the abuse of bleeding, or the effect of any considerable accidental hemorrhage.

Paleness and lividity of the patches, the formation of petechiæ, prostration of strength, and other adynamic symptoms, are occasionally, and during certain epidemic morbillary constitutions, the most frequent characteristics of measles. Blisters applied, for short intervals, to large surfaces of the body, camphor, Virginian snake-root, and preparations of bark internally, are the remedies which have been most generally recommended in this *malignant measles*; a form of the disease not very often seen at the present day.

In measles, accompanied by very severe *catarrhal* symptoms, and in the disease where the bronchial affection is very great, whilst the eruption is but scanty, and still more, whenever suffocating dyspnœa, without symptoms of pneumonia, give cause to apprehend an attack of pseudo-membranous bronchitis, an emetic of the tartrate of antimony, or ipecacuanha, on the second or third day of the disease, will be found sensibly to lessen the symptoms of inflammation in the air-passages, and to favour the development of the eruption. The same means have been recommended, in a general way, to recall the eruption when it has chanced to have receded. I have had more frequent recourse to blood-letting, to the warm bath and blisters, when these serious cases have occurred in my own practice. (b)

During *convalescence*, a spontaneous and passing diarrhœa has sometimes appeared to aid recovery from secondary inflammations of the conjunctiva, of the larynx and of the lungs. By leaving this evacuation unchecked, in every case, we should frequently run the risk of seeing our patient perish, under the drain and irritation of obstinate inflammation affecting the mucous membrane of the cæcum and colon,—diseases much more frequent than simple serous and critical diarrhœa in measles. With a view to prevent or to combat secondary diseases, however, some experienced practitioners have advised us to imitate the process of nature, and to make use of the mildest purgatives, such as a solution of manna, of cream of tartar, &c., in the decline of the disease. This practice I have adopted in every case where the organs of digestion have escaped or been very slightly affected during the course of measles.

When, in spite of this precaution, morbillary catarrhal affections remain stationary, or continue beyond the usual period of convalescence, blisters as rubefacients, applied for a short time to the breast, or kept open on the arm or thigh, are always of service. (c) The diet of children, under measles, requires to be carefully watched. I have often prescribed asses' milk, in those cases of severe bronchial affection when there seemed reason to fear that the exanthematous disease might cause or hasten the development of tubercles in the lungs.

(a) In children of strumous habits and whose hygienic condition is unfavourable, ophthalmia from measles is a protracted and obstinate disease.

(b) Tartar emetic is often borne in gradually increased doses at short intervals in these cases, and is productive of excellent effects.

(c) Careful diagnosis pointing out the seat of phlogistic irritation—in the bronchia or lungs—recourse should be had to local blood-letting, by leeches or cups for its removal, antecedently to the use of blisters or rubefacients.

The period at which the contagion of measles ceases to be subject of alarm, is not rigorously ascertained. Isolation, which is the only prophylactic means we know, should be extended to about the twentieth day. In epidemic measles of a severe and malignant kind, prudence suggests the propriety of removing children from the theatre of the epidemic. When the disease is of a favourable kind, however, far from dreading it, we have been even advised to inoculate those who do not contract it naturally, in the hope of still further increasing its mildness, or of protecting the constitution against the visits of a more serious infection at a future time.

#### Historical Notices of the Disease and particular Cases.

251. Rhazes<sup>1</sup> does not speak of measles as a new disease, but was one of the first who described it accurately. He also distinguishes it from variola by a particular name (*hasba*). The learned and laborious researches of Willan<sup>2</sup> do not, in my opinion, prove that this disease was known to the Greek and Roman physicians, nor that it had been seen in Europe during the fifth and sixth centuries. Constantinus Africanus says it was first observed in the eleventh century, and described under the name of *morbilli*. Rhazes, Riverius and Sennertus have maintained the affinity of the measles and small-pox. Hoffmann<sup>3</sup> and Gruner have considered measles as a particular kind of exanthematous catarrhal fever. Sydenham<sup>4</sup> has given a good description of its two principal forms—*morbilli regulares*, *morbilli anomali*. Some phenomena, such as the *slowness of the pulse*<sup>5</sup> during the period of desquamation, and the particular appearance of the matters expectorated,<sup>6</sup> have given occasion to observations that are useful. Interesting remarks have been published upon *congenital measles*,<sup>7</sup> on the recurrence of measles,<sup>8</sup> on measles without eruption, (*morbilli sine morbillis*),<sup>9</sup> the occurrence of which cannot be disputed. We have, also, much excellent matter on *epidemic measles*,<sup>10</sup> on its complication with *pneumonia*,<sup>11</sup> with *severe dyspnoea*,<sup>12</sup> with *arachnitis*,<sup>13</sup> with *gastritis* and *enteritis*,<sup>14</sup> with *ecchymosis*,<sup>15</sup> with *variola*,<sup>16</sup> with *vaccinia*,<sup>17</sup> on measles occupying *one side of the body only*,<sup>18</sup> and on a variety of the disease—*rubeola varioloides*—probably a complication with papulæ or accidental vesicles;<sup>19</sup> lastly, on the most common *secondary diseases*, such as inflammation of the thoracic or abdominal viscera, and others fortunately of rarer occurrence, such as

amaurosis and anasarca connected with the particular condition of the kidneys, and state of urinary secretion referred to by Dr. Bright.<sup>20</sup> In the treatment of measles, we have also particular researches into the beneficial effects<sup>21</sup> and into the ill consequences<sup>22</sup> of blood-letting, remarks on the use of *blisters*<sup>23</sup> in the anomalous disease, on *emetic-cathartic medicines*,<sup>24</sup> on *cold lotions*,<sup>25</sup> on the cure of *measly ophthalmia*,<sup>26</sup> on the *inoculation of measles*,<sup>27</sup> on measures signalized as *preservative* from its attacks,<sup>28</sup> and on the mortality which it caused at Paris in 1830.<sup>29</sup> The dissertation of M. J. M. R. Lefort,<sup>30</sup> and the treatise of M. Roux,<sup>31</sup> are worthy of being particularly consulted.

CASE X. *Hemorrhagic measles*.—Laury, admitted 10th of July, 1828, has complained for three or four days of headache, general pains in the loins, irregular chills, sense of heat in the fauces, and difficulty of swallowing, lachrymation, symptoms of cold, redness and swelling of the pendulous velum of the palate and tonsils, cough with little expectoration, considerable heat of skin, which, in the anterior and posterior thoracic regions is the seat of a violet-coloured eruption forming small arcs of circles in no great number, and, as yet, not very well defined. A few scattered vesicles are, further, distinguishable on the dorsal region. On the 12th the patches of eruption had increased in number; they evidently occurred under the form of parts of rings incompletely separated from each other by intervening portions of sound skin. These patches, of a deeper red than those of common measles, and rather resembling petechiæ, were numerous and scattered over the whole surface of the body. They could not be made to disappear entirely under the pressure of the finger. Other symptoms as before; chest sonorous; a little mucous rattle; expectoration white, compact, homogeneous, and surrounded with a little transparent fluid; pulse not much affected; belly soft, and bowels torpid. (*Diluent, cough julep; low diet.*) 13th.—The patches of the face disappeared on pressure; those of the trunk and other regions did not alter under the finger. They were not of quite so deep a hue on the breast as before, but on the trunk they appeared almost black, and, except in the circular arcuate arrangement, exactly like the stains of purpura hemorrhagica. The eyelids now began to desquamate. Next day, 15th, the colour of the eruption, although not quite so deep as it had been, was still remarkably dark. 18th.—A slight, and by no means troublesome cough, is now the only symptom of the disease that remains, except the peculiar colour of the skin in some districts, which, however is becoming every hour less and less livid. 24th.—The eruption was now extremely pale, and had assumed a yellowish tint. The truly hemorrhagic spots were still apparent; but the disease was virtually gone; to guard against accidents, however, the patient was not allowed to leave the hospital before the 1st of August.

CASE XI. *Measles; croup; death: loaded state of the left, inflamed condition of the right lung. Inflammation of the mucous membrane of the small intestines and colon; idiotism; brain apparently healthy.*—T\*\*\*, five years of age, was admitted into the hospital for children on the 4th of March, 1825. This child, though well-grown, was idiotic. According to the story of the parents, he had for three years been subject to violent pains of the head, and occasionally to attacks of vomiting. A common cynanche tonsillaris, for which advice had been sought a fortnight before, had yielded to a few leeches to the throat and common treatment. Since leaving the hospital, however, the child had been affected with a troublesome cough; he had been convulsed also; had vomited; and on the 13th of March, after his second admission, an eruption showed itself on the face, which was

held to be measles. 14th.—The eruption now covers the entire surface of the body; cough dry, pulse rapid, skin hot, eyes watery, bowels relaxed (*mucilaginous drink, cough julep.*) 15th.—(*The third day of the eruption.*)—Symptoms running high, bowels still relaxed; eruption bright, and confluent on the face. 16th.—Matters much in the same state. The thorax not examined this day, the child crying so bitterly when touched. In the evening the voice had become quite croupy; the pulse quick (*eight leeches to the fore part of the larynx, mustard plasters to the legs.*) 17th.—The leech-bites bled freely; still the respiration is exceedingly oppressed; diarrhœa continues; pulse weak and filiform, great prostration, the measly eruption still distinct, but pale (*two blisters to the legs.*) The respiration gradually became more difficult, the patient ceased to cough, and died about noon. *The body opened on the 19th.*—Traces of the eruption are still visible over the greater part of the surface of the body. The subcutaneous cellular substance and inner surface of the cutis do not appear injected. The form and consistence of the brain and cerebellum and spinal cord offer no peculiarity that could serve to account for the existence of the idiotic state. The upper part of the larynx was covered by a soft yellowish pseudo-membranous exudation; a small quantity of the same substance was also found about the lower part of the trachea, and first divisions of the bronchi. The mucous membrane of the larynx, trachea, and bronchi, was everywhere of a uniform violet-red hue. The lobes of the left lung were gorged; the middle lobe of the right lung was hepatized; the other two lobes were healthy. The heart was natural; the mucous membrane of the stomach was covered over by a thick mucus. The pyloric orifice was very narrow. A few rosy arborescent spots were found on the mucous membrane of the small intestines, which became more and more numerous as the ilio-cœliac valve was approached. The mucous coat of the large intestines was of a deep red colour, more especially about the sigmoid inflexure of the colon, and in the rectum. The mesenteric glands were red and enlarged; the other viscera seemed free from disease.

CASE XII. *Measles, pseudo-membranous bronchitis, pneumonia.*—L\*\*\*, fourteen years of age, about the beginning of the month of February, 1825, caught a slight cold. On the 15th, all the precursory symptoms of measles were apparent; weeping of the eyes, coryza, sneezing, cough, &c. 16th.—Great heat of skin, quickness of pulse, headache, anxiety about the præcordia, frequent and dry cough. 17th and 18th.—Same symptoms continue. 19th.—The eruption of measles appears over the face, the trunk and the limbs, in succession; crepitation, in a slight degree, in the lower third of the right lung; quickness and hardness of pulse, tongue red and dotted, frequent and noisy cough. (*Venesec. ad 3viii, mucilaginous drink, cough julep.*) 20th.—Paleness of the exanthema, frequent cough, scanty mucous expectoration; mucous rattle in the two lower thirds of the right lung; rather sonorous rattle in the upper third of the left lung; breathing short and very quick, pulse hard and very frequent. (*Venesec. ad 3xii, mucilaginous drink.*) 21st.—Cough less troublesome, respiration less oppressed; nevertheless, the rattle is heard over the same extent as yesterday; the eruption has disappeared, leaving no other trace of its former presence than some slight show of desquamation on the face; the tongue is white and less beset with red points. 22d.—The breathing is again more rapid; the patient, suddenly and at frequent intervals, suffers fits of great oppression; the rattle less distinct, and the respiration more obscure, in those parts of the lungs where it had hitherto been heard; almost complete absence of the respiratory murmur in the posterior and inferior parts of the right lung (*fifteen leeches upon this place.*) 23d.—Attacks of suffocation more frequent; orthopnœa, face slightly livid, lips blue, pulse 130 per minute, very small; death at five o'clock in the afternoon. *Examination of the body.*—Encephalon healthy; the mucous membrane of the pharynx, larynx, trachea and bronchi of a red colour, more remarkable opposite those points where the rattle had been heard during life; whitish membrane-like concretions, somewhat less consistent than the false membranes of croup, fill the ramifications of the bronchi, which are distributed to the two superior lobes of the lungs. Gorging and first stage of hepatization of the lower and posterior portions of the right lung, all the remaining parts of which crepitate. The left lung is crepitant, and adheres at the

top to the pleura costalis. The mucous coat of the stomach was of a dirty white colour. There were a few red spots towards the end of the ilium. The other abdominal viscera were sound.

CASE XIII. *Inoculated measles.*<sup>1</sup>—A child, seven months old, having a copious eruption on the head and a discharge from behind the ears, was inoculated the 21st of March, 1758. On the seventh day after the operation, the child began to be unwell; he was slightly feverish, had heat of skin, was restless, sneezed several times, but did not cough oftener than six or seven times in all, and had no affection of the eyes. On the 29th the eruption began to appear, and by the 3d of April the child was again quite well.

On the 6th of July, 1758, another child, eighteen months old, and of a very delicate complexion, was inoculated. *First day of the disease*, fever and dryness of surface; *second and third*, patient better; *fourth*, cough and sneezing during the day; slight nausea; *fifth*, some cough during the night, sneezing, great dryness of skin, anorexia; *sixth*, cough more troublesome, and sneezing; several patches of eruption appear in the morning, but they almost all recede. *Seventh*, the patches are very numerous over the ribs and on the thighs, where they are almost confluent. They are, however, more *distinct* than in natural measles; the eyes scarcely water; thirst; sneezing at long intervals; cough more frequent. *Eighth*, bowels relaxed. *Ninth*, purging gone; the patches disappear; neither cough nor sneezing.

## SCARLATINA.

Vocab. *Purpura; Rossalia; Morbilli confluentes; Scarlatina; Scarlet Fever.*

252. Scarlatina is a contagious exanthematous disease, which, after one or two days' continuance of fever, is announced by an eruption of small red points, which are soon replaced by large irregular patches of a scarlet or strawberry-red colour, extending to almost the whole surface of the body, accompanied by sore throat, and ending in desquamation to the end of the first week.

253. This disease presents several varieties of character in its symptoms, which may be referred to four principal forms: *scarlatina simplex*, *scarlatina anginosa*, *scarlatina sine exanthemate*, *scarlatina maligna*.

1st. *Scarlatina simplex*, Willan.—(*Scarlatina benigna et regularis*). First period (*incubation*). A sense of weakness and of general uneasiness, nausea, and transient chilly or shivering fits, speedily followed by heat of surface and a considerable degree of thirst, are the most usual precursory symptoms of the eruption. Headache, inclination to vomit, or actual vomiting, bleeding at the nose, drowsiness and other indications of affection of the nervous system, are occasionally experienced in addition. These first symptoms, which come on at any hour of the day, commonly increase in severity towards evening and during the night. (a)

2d. (*Period of eruption.*)—On the *second day* from the attack of the disease, which corresponds with the fifth or sixth of the infection, the face becomes swelled; small spots, not prominent, by no means of a very bright red at first, but subsequently of the most vivid hue, separated by intervals of the skin preserving its natural colour, appear in great numbers on the face, the neck, and the breast. Within twenty-four hours an eruption of the same kind is thrown out over the whole body, upon the lips also, the tongue, the palate, and the pharynx. On the *third day* the greater number of the interstices which have been mentioned as left between the small spots of the eruption, have disappeared, and are replaced by large dotted patches, irregular in their shapes, and ragged or serrated on their edges. The exanthema becomes continuous on the cheeks and limbs, surrounds the fingers, and acquires the scarlet colour which characterizes it. A few papular elevations most commonly arise at the same time on the hands, the chest and the extremities. The skin, which is much hotter in this

(a) I have seen a child sicken after a breakfast eaten with its usual appetite, be seized with vomiting at noon, and in the afternoon manifest a distinct scarlatina eruption.

<sup>1</sup> Home (F.). Medical facts and experiments, 8vo. London, 1758.

than in any other of the exanthematous diseases, is now burning, itchy, parched, and tender to the touch. Its surface, generally smooth, is in some places rough, like the skin of a goose—(*cutis anserina*),—a peculiarity especially remarkable about the outer and hind parts of the arms and thighs; the hands and feet, where the redness is commonly intense, are swelled, stiff and painful. The efflorescence of mild scarlet fever is rarely general; on the trunk it is in large patches, dotted as it were around their margins, and very various in their outlines. The scarlet colour is more vivid and more permanent about the groins, the buttocks and the folds of the articulations than on any other parts of the body. The eruption is less vivid in the morning than during the night, and is always deepest towards evening, especially on the third and fourth days. To make use of an expression of Huxham, the surface of the body appears to be strained with raspberry-juice, or dyed red. The fever commonly declines after the appearance of the eruption.

Third period.—On the fifth, and at latest on the sixth day, the eruption of scarlet fever begins to grow pale; the redness quits the parts affected in the same order in which it appeared; the puffing of the face becomes less, the interstices that separate the patches grow larger, and the colour of the latter fades. By the seventh day, the characters of the exanthema are already far from distinct. From the fifth day, slight desquamation, preceded by pruritus, takes place from the neck, the temples, and the chest. On the eighth and ninth, large pieces of cuticle are detached from the skin of the hands, fingers, feet, and other quarters of the body.

Before the eruption appears, and on its first breaking out, the pulse is full and frequent; the surface of the tongue is covered with a whitish fur, and its edges are red; the pharynx presents a dotted erythematous appearance; the tonsils are little swollen; sometimes the eyes are injected, sparkling, and humid; the sleep is disturbed and broken by dreams. These symptoms present a marked remission on the second or third day of the eruption; sometimes the tongue then throws off its coating, when its surface appears of the brightest red.

At this period, scarlet fever, of a favourable kind, often exhibits a rather remarkable phenomenon (*reversio*). After a febrile paroxysm, the skin is perceived to be covered anew with red spots, less numerous and of smaller size than those of the first eruption. This renewal of the disease does not continue long, and is terminated by a more or less copious perspiration.

The eruption of simple scarlatina sometimes takes place without any sensible precursory symptoms.

2. *Scarlatina anginosa* (*cynanchica*, Cullen).—The preliminary symptoms are more violent in this form of the disease than in the last. A sudden sense of stiffness in the muscles of the neck and lower jaw often ushers in the attack. On the second day, the fauces are inflamed, the voice is hoarse, swallowing is difficult and painful; the lining membrane of the mouth and fauces is of the same bright red as the general integuments. Some days, and often on the day after the attack, the anterior pillars of the velum palati, the tonsils and fauces become covered with a thick viscid fluid, or with flocculi of a pultaceous, gray, yellowish-white, or caseous-looking matter, similar to what is observed in certain cases of cynanche tonsillaris. These exudations, of various colours and consistencies, often form a kind of uniform coating over the fauces; they differ from patches of coagulable lymph, by being softer; they may also be scored with the point of a probe, and removed upon the end of the finger without pain. These pultaceous or curdy concretions are renewed from day to day; they often spread over the lateral parts of the pharynx and extend even into the œsophagus. I am not aware that any thing of the same kind has been observed after death, in the larynx and trachea. They have been called *aphthous crusts*, and have been erroneously supposed, by Fothergill and Huxham among others, to be eschars and ulcers. When the tonsils happen to be unequally swelled and to have bled a little, these incrustations are sometimes tinged of a brown or black colour, and put on the semblance of foul ulcers, in so much the more as the breath is then apt to become tainted. More attentive examination, however, shows that the pultaceous incrustation is very easily detached from the mucous membrane of the fauces, but never in masses or flaps, as in cynanche with exudation of coagulable lymph.

The parts once cleansed by gargles and mucilaginous drinks, never exhibit any loss of substance or any trace of ulceration, circumstances which both occur in gangrenous sore-throat.

On the second, third, and fourth days, the temperature of the skin rises to 41° and even 42° of the centigrade scale. The pulse also is then frequent, but not very full; the state of the mouth changes, the tongue is of a bright red, the papillæ very distinct; there are nausea, vomiting, diarrhœa or constipation, cough without expectoration, sneezing, coryza, guttural voice, and frequently hemorrhage from the nose, with some oppression of breathing.

The eruption does not generally appear so soon as in scarlatina simplex; it is often not visible before the third day, and does not spread so constantly over the whole surface of the body. It consists of isolated patches of a scarlet or raspberry colour, situated over the back, the flanks, the neck, the breast, and the limbs, and very regularly about the wrists. The eruption sometimes vanishes entirely on the very day of its appearance, and comes out again after an interval of longer or shorter duration. In this variety, the inflammation of the skin is very commonly attended with a decided tumefaction of the cellular tissue, especially in the face, and in the fingers, the flexion and extension of which are impeded. Lastly, the entire duration of the efflorescence is longer in this variety than in scarlatina simplex, and the subsequent desquamation less regularly performed; it is, indeed, scarcely appreciable when the eruption has disappeared suddenly, and when the exanthema has been very intense, is sometimes protracted beyond the third week.

Scarlatina *anginosa* may be complicated with pneumonia, or an affection of the brain, and thus become fatal. Secondary diseases are also more frequent after this form of the disease than after scarlatina simplex.

3. *Scarlatina maligna*.—Scarlatina sometimes occurs with symptoms of a still more formidable description. It commences like scarlatina *anginosa*, but in the space of two or three days is characterized by symptoms of extreme severity. Often, too, it is ushered in by a fixed pain in some part of the body, a phenomenon which De Haen observed to be of the very worst augury in the epidemic constitution of 1777–1778, described by Meza. To a violent shuddering fit (*horror*) succeeds a burning fever, unquenchable thirst, headache, quick and hard pulse, heat and pain of throat, vomiting and diarrhœa, coma or delirium, followed, three or four days after, by patches of eruption more raised than in scarlatina simplex, and sometimes accompanied by bloody urine.

The efflorescence in this variety is tardy in its appearance; its colour is pale or livid; it is sometimes mixed with petechiæ, its duration is indeterminate; it may appear and disappear once and again. The pulse is small and irregular; the teeth and tongue are covered by black or brown sordes; the eyes are watery and much injected; a fetid discharge is sometimes poured out from the nostrils; the cheeks are of a deep-red colour; there is at the same time deafness, in adults delirium, in children coma and jactitation; the breath is tainted, the breathing noisy and laborious, owing to the thick and viscid mucus adhering to the parts about the fauces; deglutition is difficult or impossible; there is constriction of the jaws, and a blackish exudation from the tonsils and neighbouring parts. Continual coma, extreme difficulty of respiration, copious diarrhœa, and the formation of numerous petechiæ, prognosticate speedy dissolution, which often takes place suddenly on the second, third, or fourth day.

The small number of patients who survive these first formidable symptoms, have now to contend with the consequences of inflammatory action in the air-passages and the digestive organs, which continues after the exanthema has gone, and with all the miseries of protracted illness. Gangrenous eschars often form over the trochanters and sacrum, which are followed by extensive ulcerated surfaces, whose cure, as it is difficult, prolongs still farther the period of convalescence. When any thing like chronic intestinal inflammation is going on at the same time, these sores are always serious, and sometimes fatal.

4. *Scarlatina sine exanthemate*.—In the epidemic scarlet fever of 1766, observed by Fothergill and by Huxham, it sometimes happened, in the cases of patients of a certain age, but very rarely in those of children, that after the most violent sore throat, there was no eruption, although the skin itched excessively, and desquamation, in various

degrees, afterwards took place. During the epidemic of 1788, observed by Rumsey, in Buckinghamshire, the soreness of throat was a symptom more invariably present than the eruption. Stoll, Aascow, Bang, Ranöe, and, very recently, an observer, as accurate as he is well-informed, Dance, have also attested the occurrence of these scarlet fevers without eruption. I have not myself seen any cases of the same kind; but, perhaps, this is owing to the rare occurrence of the complaint within the walls of the hôpital St. Antoine and de la Charité, where adults only are admitted, as well as to the difficulty of seizing every feature of a disease during its epidemic prevalence, necessarily experienced by him who is engaged with practice in a great city like Paris.

254. Whatever the form under which scarlatina shows itself, the eruption may be complicated with other inflammatory affections of the skin. From the fourth to the fifth day of the exanthema, there is often observed, upon the neck, the arm-pits, and sometimes on other parts of the body, an eruption of *sudamina*,—of small semiglobular vesicles, containing a pearly or transparent fluid, which is quickly absorbed, or flows out when the cuticle is ruptured; this is the *scarlatina miliaris* of Frank. Sometimes, too, pruriginous eruptions,—such as urticaria,—are observed at the commencement of the desquamation. Complications of scarlatina with measles, erysipelas, and the pustular inflammations, are more uncommon.

255. *Secondary diseases*.—During convalescence, from the fourteenth to the fifteenth day of the disease, and, occasionally, later, anasarca is apt to make its appearance; and this is a phenomenon which deserves to be particularly studied. The affection occurs most frequently during the winter season, and among children, in consequence of exposure to cold. Its approach is announced by a feeling of languor, of depression of spirits and peevishness, by want of sleep, and scanty and high-coloured urine, which often resembles the washings of meat. The face, and especially the eyelids, become swollen, and the œdema, spreading to the lower extremities, is not long of becoming general. All authors are of one mind as to the serious nature of this anasarcaous affection. According to Plenciz and De Haen, it is much more destructive than the primary disease; and these writers, as well as Stoerck and Withering, look upon the dropsical affection as a second period in the disease, and almost as one of its distinguishing characteristics. The affection is variously ascribed, by different authors, to the effects of cold, to an imperfect crisis, and to an affection of the kidneys.<sup>1</sup> Blackall and, more recently, M. Peischer, have shown that the urine was often albuminous during the continuance of the anasarca; and there is enough in these scattered remarks, when united, to make us inquire whether this species of anasarca be not really a variety of the dropsical affection lately made known by Dr. Bright, which Drs. Gregory and Christison have done so much to illustrate by new facts, and in the investigation of which I have myself spent some time.<sup>2</sup> In fact, like the disease described by Dr. Bright, the anasarca of scarlatina is almost always produced by exposure to cold and moisture. On the invasion of both diseases, a particular change in the qualities of the urine is often observed; this fluid becomes brown in colour, albuminous, and loaded with cruor. Both are very formidable affections; they both occasionally end in hydrothorax, and in hydrocephalus, and are very different from those passing dropsies proceeding from some obstruction to the current of the blood, the mechanism of which M. Bouillaud has so well explained. I have never had an opportunity of examining the organs, and particularly the kidneys, of an individual who has died from anasarca following scarlet fever, although I have very frequently had such opportunities in reference to the disease described by Dr. Bright. I observe no dissections of such cases among all those published by Dr. Gregory; but there is, during life, so perfect an identity in the phenomena of these two diseases, that *post-mortem* examination would, most probably, show them to be of the same nature. (a)

(a) Lesions of the kidneys from scarlatina are not as common as might be anticipated from the presence of anasarca and albuminous urine.

<sup>1</sup> Ueberlacher, Abhand. vom Scharlach Fieber, S. 378. Wien.

<sup>2</sup> Tissot. De l'hydropisie produite par l'affection graneuleuse des veins.—Paris, 1833, 4to. [Also Traité des Maladies des Reins et des alterations de la Secreion Urinaire, &c., avec un atlas, folio, tom. ii. 1839–40.]

As consequences of scarlatina, we also frequently observe inflammatory affections of the eyes, of the ears, of the bronchi, of the mucous membrane of the bowels, of the parotid glands, and of the testes in the adult, and swellings of the glands of the neck and groin in children; but these diseases are rather adventitious than secondary.

256. *Structural changes*.—When death has occurred on the second day from the invasion of scarlatina, I have found no more than a little redness in the mucous membrane of the bronchi; all traces of the eruption had disappeared. When death took place on the third day, the mucous membrane of the fauces, of the trachea, and of the bronchi, presented a uniform red tinge; the vessels of the brain appeared loaded, and the vascular reticulation of the pia mater was injected; the mucous covering of the stomach sometimes looked red, and was studded with slight ecchymoses. The lesions discovered during the second period of the disease, are very nearly the same, with this difference, that they are much more evident; I have found redness, and sometimes a collection of pus, in the tonsils and cellular substance beneath the mucous membrane of the upper part of the larynx; the mucous membrane of the trachea and bronchi was either red or of a uniform livid hue; the minute vessels of the cerebral and spinal pia mater were injected; their interstices occasionally presented slight ecchymoses, whilst the lateral ventricles were filled with serum. Sometimes, however, I have been unable to discover any lesion which could account for the symptoms of cerebral disturbance observed during life. The blood in scarlatina has been little examined. I do not know whether, as in measles, it possesses contagious properties. I have sometimes met with extraordinary evolution or swelling of the glands of Peyer, and, indeed, of the generality of the intestinal mucous follicles, as also with ecchymoses into the substance, and effusions of blood upon the surface of the mucous membrane of the stomach and intestines. I have, further, observed, but more rarely, effusions of blood or of purulent matter into the cavity of the pleura, which, in the rapidity of their evolution and progress, seemed to partake of the nature of the disease they accompanied. The mouth, the nasal fossæ, and the fauces, often exhibit the redness and changes proper to cyananche, with exudation of creamy-looking matter upon the surface. (a)

257. *Causes*.—Scarlatina is a contagious disease, but in a less degree than measles. Petit-Radel tried in vain to communicate it by inoculation, but we are told that Stoll succeeded in such an attempt; J. Frank tells us that it may be transmitted from the human subject to the lower animals,—as to dogs. Scarlatina principally affects children and youths; adults are more secure from its attacks; it very rarely happens that the same individual is affected twice. Out of two thousand cases, Willan did not know of a single instance of its recurrence. When the first edition of this work was published, I was in the same position myself, but since that time one case has come to my knowledge: a young man whom I had attended, several years before for scarlet fever, whilst recovering from pneumonia, in the treatment of which blood-letting had been employed to a great amount, contracted the disease through the ordinary channel of contagion.

All are not alike apt to be influenced by the contagion of scarlet fever; and every variety of circumstance is not equally calculated to make it efficient. It attacks females more readily than males. Some individuals, after having been exposed with impunity several days to the contagion of this disease, have been seized with it at a later period from simply coming into contact with persons who had visited patients labouring under the malady. Scarlatina almost always prevails as an epidemic, and most frequently about the period of the equinoxes. In winter it rages when the atmosphere is variable, damp, cloudy and cold, and at other seasons after heavy rains succeeded immediately by great heat.

The epidemic scarlatinas that have prevailed at different times, considered severally, have always a distinguishing character that approximates or seems to separate them from one or several others.

(a) Armstrong says that in nine cases out of ten the air passages are inflamed in scarlatina, and Mr. Hamilton, in his account of the epidemic as it appeared in Edinburgh in 1832, bears him out in this assertion.

Certain epidemic scarlatinas, for example, have been remarkable for their character of mildness. A fixed pain was one of the serious symptoms of the epidemics observed in 1777 and 1778, at Copenhagen, by Meza; a malignant scarlatina was described by Sennertus, in 1619, and the same form of the disease was prevalent in Saxony, in 1695 and 1697: Morton has left us an account of an epidemic scarlatina accompanied with buboes, and swelling of the parotid glands; the epidemic of 1748 and 1749 which occurred at the Hague, was connected with ulcerations of the throat and genital organs; in the epidemic of Upsal, 1741, described by Rosen, affections of the parotid glands were not held an unfavourable symptom; the epidemic observed in 1751, by Navier, at Chalons-sur-Marne, and that which was seen at Vienna, in 1770 and 1771, by De Haen and Kirchvogel, presented all the characters of scarlatina maligna.

Certain epidemics, however, have had a mixed or complicated character; such was the one described by Lorry in 1777. That observed by Stoerck, at Vienna, in 1759, was accompanied by a miliary eruption; the epidemic of Cephalonia, described by Angelo Zullato, was remarkable for its complication with bilious and wormy affections.

258. *Diagnosis.* Scarlatina differs from measles in its preursory symptoms, and by the scarlet hue of the eruption, the patches of which are much larger, whilst their shape is much more indeterminate. Neither do they, like measles, present those slight elevations circularly disposed and sensible to the touch. Scarlatina is further distinguished by the inflammation of the fauces that almost constantly accompanies it. In measles, three or four days before the eruption appears, the patient suffers from cold in the head, from sneezing, and a dry and hoarse cough; the eyes become moist and full of tears; in scarlatina the eyes are hot and inflamed, and the patients complain particularly of pain in the throat. Measles shows itself on the fourth day of attack, at first on the upper parts of the trunk, and extends gradually to the rest of the surface; the eruption of scarlet fever on the second day pervades the whole of the body. Measles most commonly leaves bronchial, ophthalmic and enteric affections behind it; anasarca more frequently follows scarlatina. According to M. Heim, scarlatina has a peculiar odour, which he compares to that which is felt in warehouses where old cheese is kept, or to that which at some distance is exhaled from the dens of lions and other beasts of prey. This odour is distinguishable from the very beginning of the disease, even before the appearance of the eruption. Measles has also its peculiar smell, which, from the invasion to about the seventh day, is bitter mixed with sweet; at a later period it becomes sourish, and precisely similar to that exhaled from the feathers of a goose stripped alive or recently killed. Scarlatina differs essentially, in many of its characteristics, from roseola, from erysipelas (231), and from erythema (221). The adventitious evolution of sudamina and of a few vesicles in scarlatina cannot render its diagnosis from sweating miliaria (*miliaris sudatoria*) difficult. In scarlatina, they are few in number, and only appear on certain regions; in sweating miliaria, they are scattered over the surface of the body generally. Lastly, the existence of a scarlet efflorescence of the skin suffices to establish a distinction between scarlatina and the inflammatory affections of the fauces with exudation of a creamy or pulsatious substance, observed in certain epidemics of scarlatina, and designated by Johnston, Withering, Stoll, and others by the name of scarlatina *without eruption*. M. Bretonneau has given an excellent account of the characters that distinguish the scarlatina maligna anginosa from angina or cynanche maligna, which he entitles *diphtheritis*. An extreme degree of derangement of the circulation, similar to that which follows on the bite of a viper, may be observed from the very commencement of scarlatina maligna; the rhythm of the respiration is not less affected; the functions of the alimentary canal are perverted, and excessive vomiting accompanies incessant diarrhoea; at the same time the disorder of the functions of the nervous system goes on continually increasing, and every thing foretells a fatal termination. The commencement of the cynanche maligna, or diphtheritis, is scarcely marked by the occurrence of febrile symptoms, or, at least, after a transient fit of fever, the pulse soon loses its frequency and returns to about its usual state. The organic functions generally, and those of voluntary motion particularly, are so little deranged, that children who are already dangerously affected by the angina maligna, display their wonted appetite for food

and continue at their play. Each of the phases of scarlatina is presented to our observation within the terms of a limited period; no term can be assigned to the successive stages of diphtheritis. Scarlatina, in its progress, has all the characters of a very acute disease; it may terminate in death on any of the days from the first to the seventh of the single week during which it is at its height (*status*); diphtheritic inflammation rather affects the chronic type, if the obstruction of the air-passages does not put a period to its continuance by causing the death of the patient. The inflammation of scarlet fever extends almost simultaneously to every part of the different mucous surfaces it invades; of an eminently local nature, it is from a single point that diphtheritic inflammation is propagated, with various degrees of rapidity, but successively, to the surfaces over which it spreads: thus whilst thick concretions, altered in their appearance, have already covered the tonsils and fauces for several days, we find, in the event of the patient sinking from obstruction in the air-passages, that the mucous membrane of the trachea and bronchi, and nasal fossae, are endued with concretions evidently of more recent dates. The inflammation of scarlatina shows little disposition to invade the air-passages; whilst diphtheritis exhibits this tendency in a very remarkable degree. In scarlatina, if the patient die within the first week, no anatomical lesion is to be detected of importance enough to account for the death; diphtheritis does not prove fatal, on the contrary, till the moment when the pseudo-membranous layers that line the air-tubes, either by their detachment or their accumulation, become a mechanical obstacle to the respiratory process; sometimes even asphyxia does not happen till many divisions of the bronchi are completely plugged up. No topical treatment, though it exert the most beneficial influence on the inflammation of the throat, abridges the duration or lessens the danger of scarlet fever; the first days of the second week bring about the desquamation of the skin, and convalescence of a more or less imperfect kind; and the patients who have reached a considerably advanced period of their recovery are not yet beyond the reach of change, nor yet safe from the ill consequences of the disease; they are still liable to be attacked with gangrenous ulceration of the skin, with convulsions, anasarca, œdema of the lungs, and numerous chronic affections, almost always accompanied by a remarkable change in the quantity of urine, which acquires a deep brownish-yellow colour, owing to an admixture of crassamentum. If, on the contrary, we succeed by local treatment, in modifying diphtheritic inflammation, the recovery of the patient is secured as soon as the local disease is at an end. The most fatal epidemics of scarlet fever scarcely cut off a fifth of the numbers attacked, whatever the mode of treatment adopted, and the mortality is generally much smaller; it is well nigh demonstrated that every one affected with angina maligna dies if the disease be left to its own course.

Let us add in reference to scarlatina as to measles, that the most important matter in a diagnostic point of view is to ascertain the measure and intensity of the affection that accompanies the exanthema, and the character of mildness or malignity of the prevailing epidemic. The greatest attention is required in examining into cases of scarlatina maligna. The delirium and other formidable cerebral symptoms seem often due to the violence of the inflammatory affection of the skin, of the fauces, or of some other organ; at times they appear to depend on congestion of the meningeal veins; but there are some cases where these phenomena, evidently independent of every kind of encephalic congestion, are still more serious and inexplicable.

259. *Prognosis.*—Scarlatina *simplex*, in a well-constituted subject, who has not recently suffered from acute or chronic disease of any kind, is without danger. A mild form of the disease may, however, become dangerous by the *retrocession* of the exanthema, occasioned either by a stimulating plan of treatment or exposure to cold. Epistaxis occurring at the moment of the eruption is reckoned a favourable symptom.

The extent and severity of the inflammation of the fauces and mucous membrane of the stomach and intestines, which so often precedes and accompanies the eruption, the character of the prevailing epidemic, and the pulmonary or cerebral affections which may supervene at different periods of its evolution, make the prognosis more or less doubtful according as these affections themselves prove severe and obstinate in their character.

In puerperal women scarlatina is commonly a serious affection. At the *Maternité*, M. Senn observed that pregnant women when first received into the hospital were seldom attacked by the disease, but that they very readily became affected by it after delivery.

260. *Treatment*.—In scarlatina *simplex* of a slight kind, the natural and regular course of the disease is favoured by the action of an agreeable and uniform temperature; spare diet is to be enjoined, diluents may be freely indulged in, and the foot bath used at night. In a strong and plethoric subject, if the heat of surface is very great, blood may be withdrawn from the arm. The patient ought not to yield to the inclination he feels to throw off the bed-clothes; and the room in which he lies is to be ventilated with caution. Neither ought he to quit his chamber or be allowed to leave the hospital until the thirtieth day.

261. In scarlatina *anginosa vel cynanchica*, gargling frequently with milk and water or some mucilaginous decoction, the detraction of blood from the arm, the application of leeches to the neck or epigastrium, of emollient poultices, in the form of a cravat, to the throat, and diluted sinapisms to the extreme parts, are generally useful measures. When perseverance in such steps does not seem longer allowable lest the natural course of the disease should be interrupted, we must have recourse to the application of a blister to the nape of the neck, and of cloths or sponges wrung out of cold vinegar and water to the epigastrium and those parts of the body where the heat is felt to be excessive.

Other methods of treatment have had numerous partisans. Currie, Withering, Bateman, Dr. A. T. Thomson and many other English physicians especially have boldly had recourse to cold affusion or the affusion of cold water in scarlatina. The patient is placed in an empty bath or washing-tub and one or two pails of cold water are poured over his head. He is then dried quickly, and again put to bed, where, should the cold continue, he should have little of some warm drink, or warm wine and water. In a few minutes the pulse becomes less frequent, the heat of surface declines, the thirst is less intense, tranquil sleep succeeds to the previous state of agitation, and is commonly followed by the breaking out of a sweat that proves of service. If the morbid symptoms recur, if the heat becomes pungent and very high, the affusion may be repeated with the effect of assuaging them again.

The fear of repelling the disease expressed by the patients or the bystanders has sometimes obliged the advocates of cold affusion, to be content with merely sponging the face, neck, chest, and extremities with cold water. The room should be ventilated at the time that the heat of the body is by this means reduced.

"We are possessed of no physical agent," says Dr. Bateman, "not excepting even the use of blood-letting in acute inflammations, by which the functions of the animal economy are controlled with so much certainty, safety, and promptitude as the application of cold water to the skin under the augmented heat of scarlatina. I have had the satisfaction in numerous instances of witnessing the immediate improvement of the symptoms and the rapid change in the countenance of the patient produced by washing the skin." (a)

(a) Long experience in scarlatina, and familiarity with this practice, induce me to coincide fully in the praises of the latter by Dr. Bateman. By no other remedy is the patient so speedily and pleasantly soothed and thrown into a refreshing sleep, as by cold or tepid affusion according to the heat of the skin and general excitement. The rules that ought to govern us in this practice, are well laid down by Dr. Thayer in applying it to the treatment of measles. I shall quote on this occasion from my work on *Baths and Mineral Waters*.

"The conditions for prescribing cold affusion in these cases were, 1. That the temperature of the body of the patient should be above 98° Fahrenheit, and that there co-existed restlessness and shortness of breath. 2. That the water for affusion should be colder in proportion as the body of the patient was hotter. Dr. Thayer was, in this respect, regulated by the table of Frélich which he always carried about with him, together with a small thermometer, the bulb of which he placed under the axilla of his patient. 3. That sponging or ablu-

Several English physicians have proposed to treat scarlatina by *purgatives* alone, affirming that they never produce the nervous symptoms, and the depression of pulse sometimes observed after bleeding. Willan employed calomel, in doses of two or three grains, combined in the beginning of the disease with the same quantity of antimonial powder. The same combination he informs us was freely administered by a physician, at Ipswich, in 1772, in large doses; and of three hundred patients thus treated none died.

To diminish the fever, heat and restlessness, the *tartrate of antimony* in emetic doses repeated every twenty-four or forty-eight hours has been recommended by some practitioners. A single exhibition of this or another emetic at the onset of the disease is a safe and, perhaps, a useful medicine; but such a mode of employing the remedy is supported neither by experience nor principle.<sup>1</sup> (a)

Two drachms of *chlorine* to eight ounces of water in the course of twelve hours has been extolled by Mr. Bathwite as a specific remedy. I have not myself tried any of these various medicines.

262. In scarlatina *simplex* and scarlatina *anginosa* complicated with violent inflammation of the stomach and intestines, of the larynx and bronchia, with cerebral or arachnoid congestions, &c., the activity of our antiphlogistic treatment ought to be in the ratio of the number and of the severity of these affections. At the onset they require general blood-letting, and the application of leeches to the throat, the epigastrium, and to whatever points the inflammation may have reached. Bleeding, however, either generally or locally is never to be carried so far as to produce the effects of a hemorrhagic condition of the system. Neither are we always to ascribe every case of delirium to inflammation of the brain or its membranes. Something must be left to the influence of time in this as in every other form of fever. We may next be called upon, as in the case of measles, to endeavour to restore the efflorescence of scarlatina by means of the warm bath and rubefacients, when it has disappeared in consequence of exposure to cold and moisture, and to give the eruption fixity, so to speak, by the agency of blisters when it comes and goes alternately. When this irregular progress of the disease is connected with paroxysms of internal irritation, as is most usually the case, the best way to fix the exanthema of the skin is to attack and subdue, if possible, these in-

tion was never to be resorted to when the little patient was in a tranquil state, or perspiring.<sup>2</sup>

"I shall here introduce the table of Frélich which will serve as a useful guide to direct the practitioner in the employment of bathing, and also as an apt illustration of the principles on which the remedial powers of the bath must rest. The greater the heat, and the higher the excitement, the colder is the water and the longer the period of immersion: a practice perfectly in accordance with the creed which admits the direct sedative power of cold, but contradictory and absurd, if we suppose with Currie and others the stimulating power of this agent.

Heat of the body by Fahr. Therm.	Temp. of the water by Fahr. Therm.	Duration in minutes of the Ablutions.	Baths.
98	90½	4	...
99½	85	4	...
100	75	4	1½ to 1
101	65 to 70	6	1 to 2
102	60 to 70	4 to 6	2 to 3
103	60 to 70	8	6 to 8
104	60	...	3 to 4
105	55	...	2 to 3
106	40	...	1 to 3
107	40	...	1 to 3
108	35	...	3 to 4
108½	35	...	3 to 4
109	35	...	3 to 4
110	35	...	3 to 4
111	35	...	3 to 4"

(a) An emetic at the beginning of the disease, and small doses of tartar emetic in its progress, where the pulse is active, is a part of a practice with which I have much reason to be pleased.

<sup>1</sup> Bateman, Synopsis, p. 77.

<sup>2</sup> North American Medical and Surgical Journal, Vol. VIII, p. 414, 415.

ternal disorders—a consummation which, unfortunately, is not always to be attained.

263. In scarlatina maligna, what therapeutic means can we hope to employ with success against delirium, and the effusion of blood into the textures of the stomach, the pleura, the meninges, &c.? Bleeding is almost constantly ineffectual; the pulse sinks with a rapidity that makes us despair, as in severe cases of dothineritis, the characteristic lesions of which are sometimes found on opening the bodies of those who die. On the other hand, the writers who have been loudest in praise of cold washing and cold affusion, tell us that in this form of the disease the remedy is of no avail. Ipecacuanha and tartrate of antimony by exciting vomiting sometimes expel the sanious phlegm accumulated in the fauces, and seem occasionally to restore the disease to a more regular type. Fumigations with vinegar, and decoctions of bark and contrayerva acidulated with simple oxymel or muriatic acid, or made pungent with the chloride of lime, or slightly stimulating by the addition of a small quantity of spirits, have very generally been recommended. Transient blisters, and sinapisms to the throat have also been held up as advantageous. Purgatives, too, and particularly calomel, in a dose of eight or ten grains, are said to have been more generally beneficial than any other means. I have not tried them myself; indeed, scarlatina maligna is a disease rarely met with, either in general practice or in the hospitals at Paris. (a)

According as the scarlatina *sine exanthemate* presents itself with the characters of simple or of complicated scarlatina, or with those of scarlatina anginosa or maligna, ought to be the variety of treatment pursued in regard to each particular case.

264. During convalescence, every possible precaution must be taken against the occurrence of anasarca. The patient must be put on his guard against exposing himself to cold; a tepid bath or two may be taken, and if the colour of the skin assumes a pallid aspect, frictions with dry and warm flannels, either unmedicated, or medicated with some aromatic or slightly stimulating powder or vapour may be practised.

When anasarca supervenes, either spontaneously or from some imprudence on the part of the patient, it ought to be attacked by general blood-letting, if the state of the constitution warrant such a measure, by the repeated use of the warm bath, by the acetate of potash in quantities of half a drachm daily, or by calomel in purgative doses.

265. Dr. Hahnemann,<sup>1</sup> having announced that during the epidemic prevalence of scarlet fever, those children and adults to whom belladonna was administered were preserved from the disease, although they had had communication with those who were attacked by it, the profession everywhere showed great anxiety to put this statement to the proof. In 1820, a violent epidemic scarlet fever having broken out at Gutersloh, none of the children to whom the extract of belladonna was administered were attacked;<sup>2</sup> the medicine was exhibited for a week. Hufeland has collected the reports of thirteen different German physicians who have tested and confirmed this opinion in regard to the preservative power possessed by belladonna against the attack of scarlet fever. M. Martini<sup>3</sup> also avows his faith in this virtue. M. Ibréliste, practising at Metz, saw twelve children preserved by belladonna from scarlatina which attacked two hundred and six, surrounded by whom they lived.<sup>4</sup> Dr. Velson administered this medicine to two hundred and forty-seven persons, of whom only thirteen contracted scarlatina. His formula was two grains of the extract in

two ounces of water, and two drachms of alcohol, a mixture of which from fifteen to twenty drops daily was exhibited. From the researches of Dr. Wagner, on the sum of the epidemics of scarlet fever in which belladonna has been prescribed, compared with others in which it was not employed, it follows that in the former the mortality was at most one in sixteen, whilst in the latter it was as high as one in three.<sup>5</sup> Whole villages kept themselves free from the epidemic by the use of the belladonna. Bernt recommends two grains of the extract to be dissolved in an ounce of cinnamon water, and during the prevalence of the epidemic, two drops of this solution to be administered night and morning to children of a year old, and to those farther advanced, one or two drops more than the number of their years. It may be urged that the continued use of belladonna during the course of an epidemic of long continuance might prove not unprejudicial. The effects of a medicine so active as belladonna, even in small doses, ought to be attentively watched. All the documents on the virtues of belladonna as a preservative from scarlet fever have been collected by Hufeland.<sup>6</sup> Schwarze, Cock,<sup>7</sup> and other practitioners have denied this preservative influence of belladonna entirely, which seems to require further confirmation.

Doctor Hahnemann discovered that belladonna sometimes produced a more or less fleeting redness of the skin, and dryness of the throat, homœopathic symptoms which, according to him, explain the peculiar properties of this medicine.

A combination in equal parts of yellow sulphuret of antimony and calomel<sup>8</sup> has been recommended as another preservative against scarlatina. The dose for children of from two to four years of age, is from a third to a quarter of a grain of the mixture added to a little sugar or magnesia; and this is repeated three or four times a day. (a)

In large towns, it is impossible to ascertain the numbers that may be attacked in the course of an epidemic scarlet fever. I have not, therefore, been in a position to undertake any experiments into the prophylactic virtues of belladonna, or of the mixture of sulphuret of antimony and calomel that has just been mentioned.

#### *Historical Notices and particular Cases of the Disease.*

266. Jos. Frank thinks that scarlatina, at least the scarlatina maligna, was known to the Greek and Arabian physicians, but the passages of Aretæus, of Aetius, and of Avicenna he refers to in support of this opinion are very obscure.<sup>9</sup> Ingrassias<sup>10</sup> was the first who, in unequivocal terms, gave the characters of this disease; he tells us it was known at Naples under the name of *Rossania* or of *Rossalia* previous to the year 1500. Forestus<sup>11</sup> ranks it among the *epidemic fevers*, and describes it under the name of *purpura*; Ballonius signalizes the epidemic that prevailed at Paris in 1581 under the name of *rubeola*, and John Coyttar,<sup>12</sup> a physician of Poitiers, appears to have seen it about 1557; since which epoch, the disease has been the subject of a multitude of observations and inquiries.

Numerous remarks have been published on the characters of scar-

(a) Dr. Sims states that the best preventive which he has met with, is a small dose of rhubarb; a few grains taken every morning so as to procure an evacuation in the course of the day.

latina,<sup>1</sup> on several forms of this disease,<sup>2</sup> on scarlatina simplex and scarlatina sine exanthemate;<sup>3</sup> on scarlatina anginosa;<sup>4</sup> on scarlatina complicated with typhoid affections,—scarlatina typhodes,<sup>5</sup> with ataxic or adynamic symptoms;<sup>6</sup> with nervous symptoms,<sup>7</sup> with arachnitis,<sup>8</sup> with encephalitis,<sup>9</sup> with affection of the parotid glands,<sup>10</sup> with coryza accompanied by pseudo-membranous formations,<sup>11</sup> with severe diarrhæa,<sup>12</sup> with miliary eruptions,<sup>13</sup> with vesicular, pustular, or bullous eruptions,<sup>14</sup> with varioloid eruptions,<sup>15</sup> on the occurrence of scarlatina in puerperal women,<sup>16</sup> and in children during teething; on the secondary diseases of scarlatina, such as anasarca,<sup>17</sup> rheumatism,<sup>18</sup> and purpura;<sup>19</sup> on the diagnosis of scarlatina and angina maligna or diphtheritis;<sup>20</sup> on the alterations of the viscera consequent upon scarlatina;<sup>21</sup> on the recurrence of scarlatina.<sup>22</sup> The treatment of scarlatina has also been the subject of particular inquiries; we have remarks on the good and on the ill effects of blood-letting,<sup>23</sup> on the virtues of chlorine,<sup>24</sup> on the influence of cold affusion or cold washing,<sup>25</sup> on the use of emetics,<sup>26</sup> of purgatives,<sup>27</sup> and particularly of calomel.<sup>28</sup>

267. The following cases will show that varicella has no influence in interrupting the course of scarlatina; that purpura hemorrhagica is not always a serious complication, and that blood-letting is sometimes an ineffectual remedy in certain cases of scarlatina, accompanied with delirium, and complicated or not with pneumonia.

CASE XIV. *Scarlatina simplex, and vesicular varicella, running their course regularly.*—Adele Despreux, 16 years of age, has been vaccinated, and has never had either variola or measles. On the 15th of October, 1830, she complained of chilly fits, general uneasiness, lassitude, and great thirst, without cough, or any pain of the abdomen; she perspired freely in the night between the 17th and 18th. In the morning she complained of sore throat, and the eruption of scarlatina became apparent. The face, arms, and part of the legs, were of a crimson red, brightest on the outsides of the limbs, and

disappearing on pressure. The tongue is white and furred, the fauces painful, and of a livid-red colour; the tonsils look slightly swelled; evacuations from the bowels; chest sounding well, no cough; thirst, skin hot, pulse frequent.—(*Low diet, mucilaginous acidulated drink.*) 19.—The efflorescence is more vivid on the lower extremities, and a fresh eruption has come out on the face and trunk, where a great number of small vesicles,—VARICELLÆ,—isolated, and transparent on their summits are distinguishable. 20th.—The efflorescence of the scarlatina declines; the throat is less red and painful; the vesicles observed yesterday are more numerous, larger, and more inflamed at their bases. The scarlatina and chicken-pox ran their course naturally, and the patient left the hospital cured on the 27th of October.

CASE XV. *Scarlatina with hemorrhagic points; vesicular varicella evolved on the parts not occupied by the efflorescence of the scarlatina.*—Mandler, aged 24, admitted 18th October, 1829, had the scars of vaccine inoculation on the arms. Three days previously he had observed that his belly was of a red colour; he had not felt unwell, had had no soreness of throat or headache, and had not discontinued his work. 19th.—Pulse natural; slight heat of the skin, bright-scarlet colour of the whole anterior part of the trunk and upper half of the thighs; less intense efflorescence on the lateral parts of the trunk, where it appears as small close-set dots or points of the colour of a boiled fresh-water lobster; the eyes, the nose, the throat, are not at all affected.—(*Mucilaginous drink; spare diet.*)—20th.—The efflorescence has extended to the neck, the face, the arms, and legs; there are, moreover, some black or very deep-coloured spots, that do not disappear on pressure, scattered here and there; the throat and velum palati are, also, of a dotted and somewhat deep-red colour—(*same prescriptions*). 22d.—This day, over the arms, the upper part of the chest, the thighs, &c., wherever the efflorescence of the scarlatina had not been visible, there is an eruption of vesicular varicella, or chicken-pox. From this period nothing remarkable occurred; the scarlatina, petechiæ, and varicella went through their usual stages, and the patient left the house well on the 10th of November.

CASE XVI. *Scarlatina, petechiæ, and epistaxis; (purpura hemorrhagica) blood-letting; recovery.*—N. Duquesne, aged 24, having had small-pox when four years old, and measles when five.—On the 17th of January he complained of wandering pains in his lower limbs, of lassitude, and, for some days, has felt a distaste and disinclination to food; he is thirsty, and has violent headache, and some pain in the eyes, though the skin is not hot. 19th.—Same symptoms, and, in addition, pain and heat of throat, and a brightish efflorescence over the legs, which, on the few next succeeding days, spread successively over the thighs, the trunk, the arms, and the neck, the face alone preserving its natural colour. During all this time there was no complaint of nausea, nor of pain of the epigastrium, and the urine deposited a thick sediment.

25th.—The neck, arms, and anterior and posterior parts of the trunk, are covered with a raspberry-red efflorescence, which is more intense about the natural folds of the skin, and the projecting parts, such as the margins of the axillæ, the ham-strings, &c., as well as the districts habitually exposed to friction, such as the shoulder and buttocks, than elsewhere. The efflorescence appears stippled or in minute points, in parts abundantly supplied with follicles, but is nowhere disposed in circlets, as in measles; the scrotum is of the most vivid colour. Besides the eruption, a great many petechiæ are visible on the legs, which, by being joined, two or more together, sometimes form spots of a larger size; the anorexia and thirst continue; the tongue is of a violet-red colour, and the papillæ are very prominent. The whole lining-membrane of the mouth and fauces is of a scarlet colour, without any trace of pultaceous exudation; pain and heat of the fauces, deglutition difficult, darting pains in the nasal fossæ, and, during the last two days, clots of blood have been discharged from the nostrils. No very urgent symptom; respiration free, some dry cough, pulse full, conjunctiva slightly injected, eyes watery. 26.—Efflorescence declining, tongue bright red, and moist; epistaxis during the night.—(*Barley water for drink, broth.*) 27th.—Renewal of the epistaxis; bowels opened twice; desquamation on the forehead of the neck. The petechiæ and ecchymoses grow pale and turn yellow. 28th.—Cough, expectoration, hoarseness, tongue less fiery, appetite. 29th.—The

redness no longer visible; the ecchymoses of the legs are of a greenish-yellow colour; the epistaxis recurs again, and more abundantly than before. Cough and hoarseness continue.—(Same plan.) From January 29th to February 9th.—Desquamation goes on over the whole surface of the body. February 9th.—Renewed epistaxis, cough, rather severe headache, pulse strong and full (Venes. ad 5xii.)—10th and following days. Better; all symptoms of the malady now disappeared, and the patient was dismissed cured on the 14th.

CASE XVII. *Scarlatina anginosa; circumscribed pneumonia; delirium; death.*—Daynal, 16 years of age; had been vaccinated, and never had either measles or scarlatina. Five days before his admission into hospital on the 12th of September, 1829, he had been seized with coryza, sore throat, headache, fever, and diarrhoea, for which several leeches had been applied to the neck. The skin was of a very vivid-red colour, which disappeared on pressure, over the abdomen and lower extremities. On the breast and upper extremities the efflorescence was stippled, and of a pale-red colour, as if it were already declining on these parts; the tongue and posterior fauces were red like the skin; the tonsils so much swelled that they touched; pain in the bowels, liquid dejections. In the evening, delirium and great agitation; the tongue dry, pulse frequent and full, heat of surface intense.—(Twenty leeches behind the ears, mucilaginous drink.) Delirium less, and not so incessant; the patient knows the bystanders; cough, hissing and crepitating rattle at the posterior and inferior parts of both lungs.—(Venes. ad 5xii, cough mixture, mucilaginous drink; low diet.) Blood strongly buffed, delirium continues, tongue parched, no stool. The leeches bled a great deal; death at 2 o'clock in the morning [of the 15th]. Dissection thirty-two hours after death. The abdominal viscera present no remarkable appearance. The lungs, gorged with black blood, crepitate throughout their whole extent, except in one small circumscribed point in their posterior part, where the tissue is hard and hepatized, and from which the blood does not flow freely as it does from other parts when they are incised. The mucous membrane of the bronchi is a little redder than it ought to be. There was a tablespoonful of serum in the ventricles of the brain, the structure of which appeared healthy. The left tonsil contained a little pus, the heart was hard, red, and enlarged.

CASE XVIII. *Scarlatina, delirium, blood-letting, death without any serious alteration of the solids.*—A. Proukis, 27 years of age, of a healthy constitution, has been unwell several days; her child, 8 years old, had but just died of the scarlet fever. On the eighth day, she herself felt very unwell and kept her bed. Next day, a dotted efflorescence appeared over the body, with pain in the throat and epigastrium, vomiting, purging, and delirium.—(Venesection, leeches to the epigastrium.) 21st of May, 1830.—Skin hot, of an uniform red colour, as if it had been stained with raspberry juice, but less intense on the face and legs; pulse full and frequent, throat painful and swollen, tongue of a crimson red; tonsils enlarged and of a deep livid hue, which extends into the pharynx, and over the velum palati; thirst, sickness, epigastrium painful, diarrhoea, chest free, agitation, low delirium. 22d.—Night restless, the patient moans, epigastrium painful.—(12 leeches behind the ears, 20 to the epigastric region; sinapisms to the feet.) 23d.—The leeches bleed freely, the delirium continues; no amendment; the eruption is paler.—(16 leeches behind the ears, lavements, sinapisms to the feet, mucilaginous drink, low diet.) Death during the night. Dissection 30 hours after death. The stomach has a few livid marblings; its mucous membrane is natural in consistence and thickness. The glands of Peyer, towards the extremity of the small intestines, are well marked, prominent, show some black dots, and are surrounded by a little redness; no particular redness, and no ulceration in the intestines; no enlargement of the lymphatic abdominal glands; a small quantity of serum in the pleuræ, without signs of inflammation, false membranes, &c.; heart natural; the blood is black, fluid, and contains some bubbles of air; the tonsils are double their usual size, and injected; the brain and its dependences are healthy.

## ROSEOLA.

Vocab. *Rash* [Rose Rash], *Measles*—false Eruption—anomalous rosy Efflorescence—*erysipelatus Rubecula, Roscola.*

268. In the first edition of this work, I followed Willan in describing, under the name of Roseola, several eruptions, acute in their nature, not contagious, transitory, and characterized by red spots, variously figured, slightly, or not at all, prominent, and usually preceded or accompanied by febrile symptoms.

Farther experience has since satisfied me that it was impossible to distinguish several species of roseola from erythema; moreover, I at one time instituted serious inquiries with a view to ascertain whether another variety, the spots of which greatly resemble those of measles (*roseola infantilis*), and which forms the principal type of this group, was not itself a mere modification or a variety of measles without catarrh. But my facts are not sufficiently decisive, nor is my mind yet sufficiently made up to allow me to destroy the group formed by Willan, under the title of roseola. At all events, the following may be taken as the characters of the various eruptions he has characterized by this name, the existence of which is not to be disputed, were they ever so variously designated, or ever so differently arranged in different nosological schemes.

1. *Roseola æstiva.*—This variety, which is sometimes preceded by slight fever, appears first on the arms, the face and the neck; within the space of a day or two it spreads to the rest of the body and causes tingling and severe itching. It appears under the form of small distinct patches, larger, paler, and more irregular than those of measles, separated by numerous intervals where the skin preserves its natural colour. Of a lively red at first, they soon acquire the deep tinge that is proper to them. The pharynx exhibits the same hue, and the patient feels a sort of roughness and dryness when he swallows. The eruption still continues bright on the second day; immediately after which it begins to decline, slight patches of a dull red continue to the fourth day, and disappear entirely on the fifth along with the constitutional disturbance.

At times this efflorescence, limited to certain parts of the face and neck, and the upper part of the breast and shoulders, shows itself under the form of very slightly elevated patches, which cause violent itching, but without the sense of prickling that accompanies urticaria. The disease lasts at most a week. The eruption occasionally appears and disappears again and again, without any perceptible cause, or in consequence of violent moral affections, or after the ingestion of spiced food and heating liquors. The recession of the efflorescence is usually attended by derangement of the functions of the stomach, by headache, a state of languor and of lassitude, which the recurrence of the eruption causes immediately to cease.

This variety of eruption usually occurs during the summer in females of irritable constitution; it is sometimes connected with the intestinal affections of the season; it seems to form a kind of a middle state between erythema and urticaria, and requires to be treated by moderate abstinence, acidulated drinks, [when these do not disagree] and occasionally by gentle laxatives.

2. *Roseola autumnalis.*<sup>1</sup> This variety attacks children in the autumn, and shows itself under the shape of distinct circular or oval spots, of a dusky red colour, which gradually increase in extent till they have attained the size of a shilling, or something less. They appear principally on the arms, and sometimes end by desquamation; this eruption is not accompanied by any great amount of uneasy feelings or of pruritus. It is evidently a variety of erythema.

3. *Roseola annulata.* This species is sometimes accompanied by febrile symptoms: its duration then is brief; in other cases, there is no disturbance among the functions generally, and the eruption continues during an undetermined period. It appears on almost every part of the body under the form of rosy rings, the central areas of which are of the natural colour of the skin. These rings are not at first more than a line or two in diameter; they enlarge gradually and are sometimes at last an inch and a half in circumference. In the

<sup>1</sup> Dr. A. T. Thomson quotes two cases from Bateman, which he refers to this variety, and which were attended by very serious febrile symptoms. Vide his Ed. of Bateman's "Pract. Syn." 8vo. London, p. 143.

morning the efflorescence is always less vivid. When chronic it has a sallow and discoloured appearance; it revives towards evening or during the night, and causes a sensation of heat, itchiness, and tingling in the skin. If it vanishes or fades, the stomach becomes disordered, languor, vertigo, and pains of the limbs, are complained of, symptoms which are generally assuaged by the tepid bath. When the eruption becomes chronic it should be treated by sea-bathing and the use of the mineral acids.

The description of this variety must be ultimately blended with that of the *erythema annulatum*.

4. *Roseola infantilis*.—In this variety the spots have smaller intervals of sound skin between them than we observe in *Roseola æstiva*. When the eruption is general, if the appearance of the disease be the only element considered in laying down the diagnosis, it is very apt to be confounded with *common measles*.<sup>1</sup> This variety of roseola attacks children when teething, or it supervenes in the course of their intestinal and febrile affections. Sometimes it only exists for a single night; or it comes and goes successively during several days, accompanied by some disturbance of the principal functions. It may also occur in succession on different parts of the body.

Whether this variety be a modification of rubeola, or be independent of that disease, it ought to be considered as the type of the group *roseola*.

5. *Roseola variolosa*.<sup>2</sup>—This exanthema sometimes occurs before the eruption of the natural or inoculated small-pox, preceding the former more rarely than the latter, in which, indeed, it is calculated to appear about once in fifteen cases, in the course of the second day of the eruptive fever, which corresponds with the ninth or tenth day after the inoculation. The efflorescence is first perceived on the arms, the breast and face, and on the following day it extends to the trunk and extremities. Its long, irregular, and diffused patches leave numerous intervals between them. More unfrequently this variety of roseola is characterized by an almost generally diffused efflorescence, slightly prominent in some points. It lasts about three days; on the second and third, the variolous pustules may be distinguished amid the roseolar efflorescence by their roundness and prominence, their hardness, and the whiteness of their summits; as soon as they appear the roseola declines. This variety of roseola has been regarded, by several inoculators, as announcing an eruption of distinct small-pox. My observations on natural small-pox, like those of Walker,<sup>3</sup> lead me to think precisely the contrary.

The eruption of roseola variolosa is, with difficulty, repelled by exposure to cold, or by cold drinks. By the earlier writers on small-pox it was mistaken for measles; a circumstance that led them to conclude that measles was sometimes turned into small-pox.

*Roseola variolosa* may be very readily connected with erythema.

6. *Roseola vaccina*.<sup>4</sup>—This efflorescence is observed to occur in several children from the ninth to the tenth day after the insertion of the vaccine poison. It comes out as small confluent patches, and sometimes diffused like those of the variolous roseola, and appears about the period when the areola is formed around the vaccine vesicle, from whence it extends irregularly over the entire surface of the body; it is not, however, so general an occurrence as the efflorescence that follows the inoculation of small-pox. It is commonly accompanied by acceleration of the pulse and great anxiety.

7. *Roseola miliaris*.—Willan tells us that this variety often accompanies an eruption of miliary vesicles with febrile symptoms.—I have not met with it in any practice.

8. *Roseola febrilis*.—In continued and typhoid fevers Bateman has observed an efflorescence making its appearance, resembling roseola æstiva, or measles. He saw this roseola occur three times at the close of slight fever. In two of these patients, the eruption only lasted two or three days; in the third it appeared on the ninth day of the fever, after a deep sleep and a gentle sweating fit. The spots, of a

bright rose-red colour, of an oval shape, slightly prominent, and smooth on their surface, thrown out on the arms and the chest, were more particularly numerous on the inner sides of the arms. The eruption was attended by no pruritus, nor any other sensation. The febrile symptoms all subsided on the same day, and the patient no longer kept his bed. Next day the efflorescence had spread; the spots had become broad and confluent, and their colour, which was weakened, especially towards the centre, had acquired a purple tinge, whilst the margins still continued red and slightly elevated. On the third day, the whole of the patches had a tendency to become livid, and on the fourth, there was scarcely a trace of them remaining, or any symptom of febrile excitement to be observed.

This variety of roseola might be described under the head of erythema, with perfect propriety.

9. *Roseola rheumatica* [*et arthritica*].—A roseolar form of efflorescence is sometimes connected with attacks of gout and acute rheumatism. Bateman attended an individual of a gouty habit, in whom a roseola, accompanied by violent fever, extreme languor, complete anorexia, and constipation, appeared upon the lower extremities, the forehead and scalp for the space of a week. The efflorescence ended on the seventh day in desquamation, and in the middle of the night the articulations of the right foot were attacked by gouty inflammation. I have seen roseola patches occur towards the end of a rheumatic seizure. Case XIX. Dr. Schönlein<sup>5</sup> has also described this variety under the title of *pelliosis rheumatica*, and assigned it the following characters: pains of the articulations and extremities, of greater or less severity, remitting, changing their place, increasing from the influence of cold, and becoming easier from the warmth of the bed; shivering fits, followed by more or less marked febrile reaction, with quickening of the pulse and increased heat of skin, which is dry.

Slight gastric symptoms with loss of appetite, clammy state and bitterness of mouth, and furred tongue are the precursors of the disease. Twenty-four or forty-eight hours afterwards, and often later, a particular eruption makes its appearance, always commencing on the legs, and sometimes going no further, but most generally coming out on the arms and shoulders at the same time: it rarely appears on the trunk, and never on the face. This eruption consists of small isolated spots, of a round shape, of the size of a millet-seed or small lentil, rarely prominent, and of a deep, or violet, sometimes blackish-red colour. The number of these spots is very variable; most generally they are neither so numerous nor so closely set as the vesicles of miliaria, or the spots of measles. The fever ceases, and the rheumatic pains either leave the patient or diminish greatly in their severity from the moment this eruption appears. Under the influence of appropriate regimen and treatment, the little spots, whose numbers may be increased by successive crops, grow pale, and the disease ends by a furfuraceous desquamation. If the course of this exanthemata is interrupted, whether by the influence of exposure to cold and moisture, or by the application of discutients, the spots disappear immediately, the rheumatic pains return in increased severity, the joints swell, motion becomes intolerable, and fever is again set up.

This disease, observed at Würzburg, where rheumatic affections are almost endemic and frequently fatal by being complicated with miliaria, attacks adults and males more frequently than females. M. Fuchs says that it is during winter and spring, when the atmosphere is cold and loaded with moisture, that he has most frequently seen this eruption.

The plan of treatment pursued at the hospital of Würzburg, consisted in the administration of tartrate of antimony when there were symptoms of gastric derangement; in the exhibition of the vinum colchici when the rheumatic pains were severe, and the use of diaphoretics, such as the acetate of ammonia and compound powder of ipecacuanha to favour the eruption. Tepid and soothing drinks alone were permitted; the regimen was simple and antiphlogistic.

Petzold,<sup>6</sup> Nicholson, and Hemming<sup>7</sup> have also met with arthritic roseola. And, to conclude, Dr. Cock<sup>8</sup> has particularly described an

<sup>1</sup> Underwood is of opinion that this error has been often committed. (On the diseases of children, vol. i. p. 87.)

<sup>2</sup> Dezoteux and Valentin have described the *roseola variolosa* under the title of *eruption anormale rosacée* (Tr. hist. et prat. de l'inoculat. 8vo., p. 238).—Baron Dimsdale has given many cases of roseola in consequence of inoculated variola (vide Present method of inoculating for the small-pox, 8vo. Lond.).

"epidemic eruptive rheumatic fever" which he saw in the West Indies.

10. *Roseola cholericæ*.<sup>1</sup> I saw this variety during the epidemic prevalence of cholera at Paris, in 1832. After the period of reaction, there occurred in some patients, especially in women, an eruption which most generally appeared on the hands and arms, and then extended to the neck, the breast, the belly, and the upper and lower extremities. At its commencement it was characterized by patches for the most part of an irregularly circular shape, of a bright red colour, elevated above the surface, and but slightly itchy. Very numerous on the hands, arms, and chest, they were less so on various other parts; in some places they were crowded together, tended to confluence, and had an appearance very analogous to the efflorescence of slight scarlet fever; in other places the aspect of the eruption was rather like that of measles, and in others even more like that of urticaria.

I have seen this inflammation complicated with an inflammatory affection of the fauces or tonsils, and its disappearance followed by an aggravation of the general symptoms, and sometimes even by death. On the chest the spots occasionally became confluent, and gave rise to patches as broad as the hand, raised above the general level, and pretty well defined. The eruption then acquired a dirty pink or rose colour. About the sixth or seventh day the epidermis cracked and was thrown off in large flakes, on almost all the places where the eruption had existed.

#### *Historical Notices and particular Cases of the Disease.*

296. I have already pointed out the principal treatises upon roseola in speaking of the varieties of this efflorescence. Orlov,<sup>2</sup> Seiler,<sup>3</sup> Heim,<sup>4</sup> and Stromeyer<sup>5</sup> have devoted themselves to pointing out the characters that distinguish it from measles and scarlatina. It is not so easy to establish a line of demarkation between roseola and erythema. No one, indeed, can confound papular erythema without fever, confined to the hands, and its prominent and distinctly circumscribed patches, with the more or less diffused, not prominent red spots of roseola, spread over almost the whole surface of the body, and appearing after a febrile attack analogous to that of eruptive fevers generally. But if a certain number of particular cases of roseola and of erythema be compared, various points will be discovered at which these two diseases meet and run into each other. Let but erythema become somewhat more general than wont, and its spots appear a little more prominent, or the patches of roseola, from some unusual violence of the accompanying inflammation, become particularly prominent, and the appearances of these two exanthemata are the same. So, the eruptions that accompanied cholera on their first appearance presented several characters that approximated them to the erythema papulatum; these, however, were soon lost, for others held pathognomonic of roseola. Lastly, roseola annularis and roseola autumnalis, which appear as chronic affections, ought evidently to be classed with erythema.

Sydenham<sup>6</sup> thought that *roseola* was a variety of *rubeola* or measles; others have imagined that there subsisted between these two affections the same relation as we trace between *variola spuria* and *variola vera*; whilst a third party<sup>7</sup> have endeavoured to prove that roseola typified a particular morbid condition distinct from all the other exanthemata.

CASE XIX. *Articular rheumatism, erythematous or roseolous eruption; muco-enteritis and bronchitis.* Marie Hautefeuille was seized, on the 7th of January, 1833, after a hard day's work, with shivering fits, which proved the prelude to a general rheumatic attack. She was treated by bleeding and the tincture of colchicum. On the 26th and 27th a *roseolar eruption* appeared on the fore parts of the breast

and abdomen, and over the lumbar region, of which four or five round and well-defined patches did not disappear completely with pressure. Upon the abdomen there is a reddish festooned or wavy zone which extends obliquely from the left hypochondrium to the vicinity of the spinous process of the illium; the lower edge of this zone is sharp and well defined; the superior is gradually lost in the healthy skin. The festoons of the lower edge are of unequal breadth. The patient neither complains of heat, itchiness, nor pain in the seat of the eruption, circumstances that sufficiently distinguish it from urticaria.

On the 28th, the rheumatic and general febrile symptoms recur with new intensity; the eruption has gone from the breast, and faded on the abdomen. 29th.—Profuse perspiration, which gave relief; the eruption disappeared from the abdomen. In the night of the 2d of February, the patient wandered, moaned, seemed drowsy, and complained of severe pain in the wrists; constipation during the last three days,—(*blisters to the forearms*). From this time forward, the rheumatic pains and fever went on declining; and the patient, after another relapse of her rheumatism and an attack of diarrhœa, left the hospital on the 25th recovered.

CASE XX. *Cholera, roseola following reaction; recovery.*—Bougal, aged 43 years, had suffered from cholera for eight days, from the cold or collapsed state of which he had hardly recovered when he was admitted into La Charité. Reaction to a greater extent was excited by a few spoonfuls of Malaga wine, and sinapisms to the extremities; and within a day or two symptoms of greater vigour were manifest.

On the 21st, an eruption appeared over the whole body, but especially on the belly and on the limbs. It is disposed in rather broad patches of an irregularly round form, and a deepish-red colour, not raised above the general level of the skin, and presenting all the characters of roseola; in some places the efflorescence is uniform, and resembles a little that of scarlatina; on the breast, however, it is exceedingly like measles; in other respects the patient's state is satisfactory, the eruption is attended by no disturbance of the general functions, and by the 27th, when the patient was quite convalescent, it had vanished without inducing desquamation.

Many instances of this kind were observed in the wards of La Charité. Two of Dr. Lherminier's patients and three of Dr. Rullier's were affected during the period of reaction in a very similar manner.

CASE XXI. *Roseola (rubeola spuria?).*—Whilst dressing G. L., aged 4 years, on the 19th of June, 1825, the nurse observed his face covered with small red spots, without elevation of the skin, and very like measles in colour. Not only were these spots evident at the period of my visit the same day, but others were distinguished on the breast and arms. The child had no fever, had slept well through the preceding night, and was playing as usual; yet the tongue was foul towards the base, and much dotted; the appetite too had fallen off for several days, and the bowels were constipated. Pressure on no part of the abdomen caused pain; the throat was not inflamed, and there was no cough or preternatural flow of tears. Two years previously I had attended this boy and his two brothers for well-marked measles, a circumstance which, considered along with the absence of several of the characteristic symptoms of measles, made me look on this slight eruption as nothing more than roseola, or the false measles of authors—(*gum-water and soup for diet*). The child slept quietly; by the 21st the efflorescence was pale; and two days after it was no longer visible; a day or two more of perseverance in the same regimen restored the appetite to its usual condition.

CASE XXII. *Roseola (spurious or modified measles?).*—I was called to see a child, 10 years of age, in the beginning of August, 1825, about 24 hours after the appearance of an eruption of small, distinct, not elevated spots, broader and more irregular than those of measles, principally scattered over the trunk and inner sides of the arms, and not attended with pruritus or pain. The fauces showed an erythematous blush, without any swelling of the tonsils, but accompanied by a slight difficulty of swallowing. The tongue was a little white at its base. No functional disorder of any other organ—(*sinapised foot-bath, barley-water, with syrup of gum, soup, milk and water*). Next day, the exanthema presented nearly the same appearance; the day after, the colour of the spots had become fainter. The health of the child was in no wise impaired, and, on the fourth day, all traces of the affection had left the skin.

## URTICARIA.

Vocab. *Aspretudo, uredo, purpura urticaia, essera, febris urticaia, scarlatina urticaia, epinyctis pruriginosa, nettle-rash.*

270. Urticaria is an exanthematous, non-contagious inflammation, characterized by an eruption of prominent spots or wheals, paler or redder than the surrounding skin, rarely of long continuance, appearing after febrile symptoms, often recurring at intervals, or becoming aggravated by fits, and always attended by the burning and itchy sensation that follows the sting of a nettle.

Six species of urticaria have been enumerated by Willan: 1st. *Urticaria febrilis*; 2d. *Urt. evanida*; 3d. *Urt. perstans*; 4th. *Urt. conferta*; 5th. *Urt. subcutanea*; and 6th. *Urt. tuberosa*. These may be all classed under one or another of two heads, according as their course is *acute*, or as it is *chronic*.

271. *Urticaria acuta*.—1st variety: *Urt. febrilis*. This is often induced by the ingestion of various articles,—such as shrimps, lobsters, crabs, the roe of certain fishes, and, above all, mussels. Salted fish, that is, dried or smoked, and various other substances,—such as the white of egg, mushrooms, honey, oatmeal gruel, bitter almonds, and the kernels of stone-fruit generally, raspberries, strawberries, raw cucumbers; several medicines,—such as valerian, balsam of copaiba, &c., may also occasion this eruption in persons predisposed to it. It would, moreover, appear to be demonstrated that it is neither to any diseased condition of the mussels that cause urticaria, nor to any change they may have undergone, as mentioned by Burrows, nor to any poisonous substances upon which they have been believed to feed at times, nor to the presence of the *cancer pinnotheres*, a small species of crab they often contain, nor to the black sediment or scum,—the *crasse marine*, of which Lamouroux speaks,<sup>1</sup> nor yet to the sea-stars on which the creature appears to live, according to the interesting researches of Beunie, from the month of May to that of August, that their property of exciting this disease is to be attributed, but rather to a peculiar susceptibility,—to an individual predisposition on the part of those who are affected.

An hour or two and sometimes much sooner after the ingestion of one or other of the articles mentioned, a weight is felt at the epigastrium; nausea, general sinking, and giddiness, are then complained of; the skin next becomes hot, and the eruption appears on the shoulders, the loins, the inner sides of the forearms, the thighs, and about the knees, generally characterized by red or whitish elevated spots, surrounded by an areola of bright crimson. The spots are commonly of an irregular shape, but sometimes circular, raised above the general level of the skin, and of very various sizes. When they happen to be extremely numerous or actually confluent in any quarter, the skin presents a general red tint, and the face and limbs are stiff and swelled in this case—(*Urt. conferta*, Willan). The eruption is attended with itching, and a sense of prickling of the most intolerable kind, especially during the night, or when the parts affected are exposed to the air. In some cases, this variety of nettle-rash is complicated with erythematous blotches. Besides the symptoms already mentioned, it is often preceded by vomiting and by purging; and spasm, choking sensations, and convulsions, have occasionally been seen added to the list; nay, there are several cases on record in which this kind of poisoning even ended in death.<sup>2</sup>—At the end of 24 or 36 hours, in the generality of cases, the eruption declines in intensity, and soon only leaves but very faint traces of its presence on the skin, which are completely effaced a few days afterwards.

The *Urticaria ab ingestis* is not always accompanied by white itchy elevations of the skin; the eruption is sometimes no more than a simple efflorescence, having the colour of that of scarlatina, and belonging rather to erythema than to urticaria. (*a*)

(*a*) For the following description of the morbid phenomena caused by eating certain tropical fish, we are indebted to an article in the *Cyclopædia of Practical Medicine*, written by D. Houghton, who himself draws largely from Autenreith (*Ubar das Gift der Fische*). “In considering the operation of fish-poison, Autenreith divides it into three forms, which may be called the choleric, the eruptive or urticose

2. *Urticaria febrilis* sometimes appears without any appreciable cause, but sometimes evidently from the effects of teething, violent or long-continued moral affections, griefs of a domestic nature, a

form, and the paralytic or collapse form. The first two of these consist of those cases in which the impression of the poison is followed by a violent reaction of the general system, and they differ from each other in that the first exhibits its effects mainly in the internal organs, especially the stomach and bowels, while the second manifests itself upon the cutaneous periphery. The third form is named paralytic or collapse, because in it the poison acts with such intensity on the nervous system as to take away all power of reaction, so that the patient sinks under a gradual exhaustion of the vital powers. It is beside our purpose to proceed further; but as we did not describe the peculiar characters of urticaria arising from fish-poisons in the general history, we subjoin here a sketch of its symptoms as constituting the second or eruptive form of Autenreith:—

“The phenomena commence usually a short time after the repast which causes them, and are ushered in by a sudden and vehement excitation of the vascular system, with a remarkable rushing of blood to the head. Whilst the carotids pulsate and the eyes grow red and turgid with fluid, the patient becomes affected with giddiness and the most violent and rending pain in the head. The eyes roll wildly in their orbits, and the eyelids are held spasmodically open. At the same time the face swells up, as do the buttocks and the limbs, and a scarlet redness or an urticose eruption overlays the whole body, accompanied with severe burning itching. In rare instances large vesicles or bullæ rise upon the skin. The patient perhaps plunges his hands into cold water to mitigate the heat, but each time he does so he experiences a peculiar stinging or prickling in them, and also in the nose. With this eruption at one time is combined fever with hard frequent pulse, tightness of the chest, and general shivering; at another violent pains in the limbs or the back, or on the other hand, with loss of sensation, and even total immobility of the limbs. The inner surface of the body also takes a part in the morbid excitement, although in a much less degree in this the eruptive than in the choleric form of the affection. Pains in the stomach and bowels soon set in, which are followed by griping, purging, and vomiting. For the most part in the milder cases, when these evacuations take place, the erythema of the vessels gradually subsides, the cutaneous swelling sinks, the pulse loses its hardness and becomes smaller, and at length a favourable sweat comes, which puts an end to this short malady. It is frequently followed by exfoliation of the cuticle.”

“In the cases, however, which occur after the partaking of the poisonous fish of the hot climates, the recovery is not so rapid, and the disease of a much deeper cast. ‘For besides that the fore-mentioned symptoms are far severer, the heat and itching being intolerable, and the eruption of an erythematous form, and the giddiness increased to a vertiginous reeling, still further phenomena appear. Dreadful cramps in the limbs and in the intestines rack the patient; a peculiar constriction with a prickling heat occurs in the pharynx, and a painful tenesmus, with strangury and retention of urine, supervene. To these, in some instances, is added an icteroid hue of the skin, and urine, and even the sweat is known to stain the linen. But what is, perhaps, the most oppressive to the patient are the shooting pains in the swollen knee-joints, wrists, and the instep, and in the periosteum of the cylindrical bones. When he has, under these symptoms, for a long time vibrated between life and death, their violence at length diminishes, and when this occurs the skin peels off in several places, the hairs fall out, and even the nails drop. Occasionally abscesses form under the skin, which, although coming at the close of the disease, have not the same critical importance as those which are so favourable a termination to typhus; and they appear to be rather a purulent dissolution of the cellular tissue under the skin than a regular phlegmonous abscess.’ (*Autenreith*, op. cit. p. 131.) Even this laborious recovery, however, sometimes fails, and the patient sinks rapidly under the violence of the symptoms, or else, having made a rally through them, dies exhausted by the weakness succeeding them, which is in some cases aggravated by successive suppuration of the skin. After death the stomach and pharynx have presented marks of a high state of inflammation.”

<sup>1</sup> Orfila. *Toxicologie gener.*, tom. ii. p. 45.

<sup>2</sup> Foderé. *Med. legale*, t. iv. p. 85.—An account of two cases of death from eating mussels, by G. Man Burrows. Lond. 1815.—Van Couver's *Voyage of Discovery*, vol. ii. p. 286.

violent paroxysm of passion, &c. The symptoms are then nearly the same as those that have just been described, save that they are not usually accompanied by vomiting and purging. The eruption is less general, and does not last through the whole course of the disease, which occupies a week at least; it appears and disappears irregularly on almost all the parts of the body, and its returns are preceded by slight febrile symptoms.

The patient, by rubbing any part of his body, can often excite spots of nettle-rash at will. These spots vary in the period of their duration from a few minutes to two or three hours. In some very rare cases the rash continues for two or three weeks.—(Urt. *perstans*, Willan.) The patients then suffer from depression, anorexia, febrile symptoms, and functional disorder of the digestive organs.—The eruption declines imperceptibly; its returns are soon characterized by nothing more than a little itching, a symptom which is itself not long in disappearing.

When nettle-rash has been very violent, and especially when the spots have continued long, some slight desquamation of the skin is occasionally observed to follow.

272. *Urticaria chronica*.—This form of the disease commonly lasts for several months, and I have known it to continue for several years, in a girl whose mother had formerly suffered in the same way. It occurs most commonly in females, and in those individuals whose skin is more than usually sensitive. A young man, a metal gilder, produced at will, and in my presence, the pale spots of urticaria, by rubbing or pinching lightly the skin of his arm or of his face. In a great number of cases this eruption has appeared to me to be connected with a deranged state of the functions of the digestive organs, and especially of the stomach, but I have also observed it in individuals who, in other respects, enjoyed the best health. The spots appear at irregular intervals, sometimes on one place, sometimes on another (Urt. *evanida*, Willan). They often show themselves, especially in one region, without being accompanied with fever, and commonly disappear again within a few hours.—The patches are, for the most part, irregular, and bear a strong resemblance to the wheals produced by flagellation; they are not surrounded by an erythematous areola, and are accompanied by no other symptom than pruritus of a very severe kind. In some cases, the pruritus is replaced by a sensation of prickling under the skin, similar to that which is caused by the prick of a needle (Urt. *subcutanea*, Willan). The eruption, which is then very scanty, consists of a few red points, but little elevated above the level of the skin, and a small number of spots, that appear at very remote intervals.—This variety of urticaria is very uncommon, and is usually caused by violent emotions of a moral kind.

Chronic urticaria, however, is sometimes seen with more serious characters (Urt. *tuberosa*, Willan). The disease does not then consist in mere slightly prominent elevations, but in true tuberosities, of various magnitudes, hard, deep-seated, extending to the subcutaneous cellular tissue, sometimes accompanied by true ecchymoses, by pain in moving the limbs, and a tense and very sore state of the skin. These tumours, which are very itchy, appear in the evening or at night, and disappear again entirely before morning, leaving the patient weak, restless, and weighed down with languor and depression. They come out more particularly on the loins and extremities; but they may show themselves over the whole of the body, cause a general swelling of the face, of the neck, and of the limbs; be accompanied by dyspnoea, irregularity in the action of the heart, and other symptoms, distressing in various degrees, which are commonly developed under the influence of a febrile paroxysm (*febris intermittens urticata*, Frank). The eruption disappears completely with the remission of the fever, and reappears with its accession.

These varieties of chronic urticaria are very irregular in their progress, and sometimes disappear for several days, to reappear, without any appreciable cause, at intervals of uncertain remoteness. Frequently it is only after the lapse of many months, and occasionally of many years, that they are got rid of entirely, either spontaneously or by the influence of some methodical plan of treatment. Turner mentions a case in which the disease continued for ten years, and Heberden speaks of one more obstinate still, in which it lasted for seventeen years. The exanthema, when it has been very intense, is followed by a bran-like desquamation.

273. Urticaria is sometimes associated with an intermittent quotidian, or tertian fever. Jos. Frank saw it under this form, at Pavia, in the months of May and June, 1794, and at Wilna, during March and April, 1812, in so great a number of instances that this intermittent with urticaria might be held epidemic.—Urticaria is sometimes connected with chronic affections of one or other of the viscera. Its association with disorders of the digestive organs is very frequent; it is less common along with diseases of the air-passages. Clarke saw this eruption occurring in women labouring under cancer of the uterus, and I have three times met with it in women of nervous constitutions after having miscarried. In rheumatic affections, accompanied by eruptions (*rheumatic eruptive fevers*), I have almost as often observed the wheals of urticaria, as the efflorescence of erythema or roseola. Urticaria may co-exist with other affections of the skin, with lichen simplex, with erythema, with roseola, and occasionally with impetigo. Wichmann has observed it complicating variola, Hufeland, measles and icterus. I have seen an unfortunate patient, labouring at once under urticaria and prurigo, whose body was covered with stains of blood and immense scratches, tearing his person with all the eagerness of frenzy.

274. *Causes*.—Besides the causes of urticaria already pointed out, there are others that require to be mentioned. Some individuals have a skin so susceptible and so much predisposed to this eruption that the gentlest rubbing and the lightest pressure are enough to bring it out. Urticaria appears during the summer, particularly in women, and individuals generally of a nervous and sanguineous temperament, and much more frequently in children and persons in the vigour of life than in the aged. Nevertheless, cold seems to have a remarkable influence on its appearance. The wheals are more particularly developed when certain parts of the body are exposed to the air. Jos. Frank tells us the disease is as rare in Italy as it is common in Russia.

Urticaria has been observed recurring periodically every month or at more distant intervals.

275. *Diagnosis*.—The leaves of the urtica dioica, urtica urens, and rhus toxicodendron, the bite of the common bug, and, according to Réaumur, the contact of the hairs of certain caterpillars, may cause an eruption of wheals which, as they are very evanescent, it is important to distinguish from chronic urticaria, generally so rebellious to all treatment. In these cases it is enough to inquire into the cause of the eruption. The white and raised wheals surrounded by areolæ, proper to urticaria, differ not only in these respects from the spots and patches of erythema, but further by the particular sensation of pricking, scalding, and itching, which accompanies them. The acute, continued, and persistent course of erythema *nodosum* distinguishes it from urticaria *tuberosa*, which usually attacks in paroxysms. The red spots and patches of roseola cannot be confounded with the dull white wheals of urticaria, and are not attended by the pruritus that characterizes the nettle-rash. Chronic urticaria is distinguished from scarlatina and measles by a great variety of particulars; nevertheless urticaria is not always well marked on every one of the parts it invades: I have seen in a case of urticaria *febrilis* in which the raised white and itchy wheals were accompanied by a vivid redness diffused over the scrotum and penis, bearing the greatest resemblance to the efflorescence of scarlet fever; on the breast the eruption had very much the look of measles; that is to say, it consisted of semi-annular patches, the skin continuing healthy within the rounds. In such cases urticaria is distinguished by its raised wheals appearing in some places, and by the absence of the other symptoms of measles and scarlet fever.

The papulæ of lichen *urticatus* are rounded, less extensive and less prominent than the spots of urticaria; their colour is deeper, they are harder, and they never disappear spontaneously. There can seldom be any danger of mistaking the papulæ or isolated tubercles produced by the bites of insects, such as the flea, the bug, common gnat, &c., which are accompanied by great itchiness, for urticaria in any of its forms. Lastly, there is so little analogy between the eruption of urticaria and the vesicles of miliaria that I am surprised Jos. Frank should have thought of drawing a parallel between these two diseases.

275. *Prognosis*.—Acute urticaria of itself presents no danger; when it follows the ingestion of poisonous substances, these may

cause symptoms of various degrees of severity, and even death; but the eruption is of course totally unconnected with this fatal termination. The chronic urticariae are often most obstinate diseases.

The disappearance of the eruption of urticaria has sometimes been succeeded by the development or increased activity of some internal, intestinal, or cerebral affection.

On the other hand, internal inflammatory diseases have occasionally appeared to decline upon the appearance of this eruption. Koch quotes a case in which a pleuritic affection was immediately removed by the development of a nettle-rash. Under other circumstances it may be critical, or appear at the time the resolution of a serious disease is accomplished. Such was the case in a man under my care, in the hôpital St. Antoine, labouring under pneumonia on both sides of the chest who, at the moment the disease began to yield, was attacked with a swelling of the parotid glands, and almost immediately afterwards by urticaria, and various clusters of the vesicles of herpes phlyctenodes on the ears.

277. *Treatment*.—The artificial exanthema produced by the stinging of nettles, very different from the febrile nettle-rash, does not generally require any treatment. If the stinging have been very severe, however, and the eruption cause irritation, sleeplessness, and other nervous symptoms, these may be allayed by local applications—bathing the parts with cold water, either alone or with the addition of vinegar, or a little of the solution of the acetate of lead.

When acute urticaria is caused by the ingestion of any substance, either venomous of itself, or rendered so by some peculiar idiosyncrasy, if vomiting have not already taken place, it must be excited by the use of emetics; some practitioners in these cases resort at once to the sulphate of zinc or sulphate of copper, on account of their very speedy effects; others, unless the case be pressing, recommend the tartrate of antimony and ipecacuanha. After the stomach has been freely emptied, if the patient be an adult, we prescribe a drink strongly acidulated with nitric acid, and twenty or thirty drops of ether in two or three ounces of distilled water, sweetened. Next day, if the bowels have not been properly opened, we may exhibit an ounce or more of castor oil, or a sufficient dose of any other aperient; and the day after that, a warm bath.

Should acute urticaria prove independent of the ingestion of any poisonous substance, or be conjoined with inflammation of any of the mucous membranes, local bleeding from the epigastric region and verge of the anus, diluents, emollient glysters, the tepid bath, with decoction of mallow leaves, or of lettuce leaves, attention to regimen, and abstinence to a greater or less degree, fulfil a double indication in such cases, and often accomplish the cure of both complaints at once. When the state of the constitution opposes no particular obstacle to the practice, it is even necessary, in a great number of cases, to have recourse to bleeding; and in *urticaria tuberosa* the violence of the symptoms may even require us to repeat the operation. The blood drawn in such cases is almost always buffy. I have found that nettle-rash fevers were cut short in many instances by bleeding; they were uniformly very advantageously modified by the practice. When the disease is accompanied by inflammation of the fauces, of the mucous membrane of the alimentary canal, or of the bronchi, blood-letting may be farther required by these latter affections; but the remedy must not be had recourse to again and again, in the hope of extinguishing the eruption, if the first abstraction of blood have not procured very manifest relief. I once caused a patient, labouring under acute confluent urticaria (*urtic. conferta*, Willan), to be bled three times in the course of eight days, without appearing to modify the state of the eruption, which subsequently yielded to cold bathing. I have seen the spots of urticaria recalled for a brief interval by the use of the cold bath, but they were no longer accompanied by itchiness or heat. When the violence of the pruritus causes almost constant insomnia, recourse must be had to opiates.

In *chronic* urticaria, inquiry must be made whether the eruption be not perhaps kept up by the habitual use of some favourite beverage, or some article of food, which of course it would then be imperative to give up. Very many patients have derived great and speedy relief, followed by perfect recovery, by abstaining from spirituous liquors, spiced dishes, &c., and putting themselves on a system of bland and regular diet.

When urticaria *intermits*, and seems to depend on a febrile paroxysm, the eruption, along with its precursory fever, commonly yields to preparations of bark and other febrifuges. I have, indeed, several times used the sulphate of quinia successfully in simple paroxysms of nettle-rash fever, which had not the character of true intermittents, and during which the eruption appeared on a great number of regions, and with greater severity than usual. To conclude; I have seen several cases of chronic and obstinate urticaria which, after having been treated in vain by abstinence and the antiphlogistic plan, yielded to a course of purgatives, alkaline baths, and the application of the vapour and hot-water douche to particular regions. Many of these cases of urticaria were hereditary, and the disease appeared without manifest cause. (a.)

#### *Historical Notices and particular Cases.*

278. Celsus<sup>1</sup> was aware that rashes sometimes appeared on the skin analogous to those that followed the stinging of nettles. The Arabian physicians described the eruption under the name of *essera*,<sup>2</sup> which has been adopted by several pathologists. The characters of urticaria *febrilis*<sup>3</sup> have been well exposed by Sydenham, Juncker and Sauvages; and the writer last named distinguished the urticaria *evanida* by the title of *porcelanea*. Observations and cases have been published on the urticaria produced by mussels,<sup>4</sup> by crabs or lobsters,<sup>5</sup> by pork, and by other alimentary<sup>6</sup> or medicinal<sup>7</sup> substances. Frank speaks of a case of urticaria complicated with sphacelus.<sup>8</sup> Michaelis has made some observations on the ill effects of its suppression,<sup>9</sup> and of its evolution as a secondary disease in variola. Some remarks have been published on urticaria *tuberosa*,<sup>10</sup> and its treatment, on *intermittent* urticaria,<sup>11</sup> and on the use of *saline baths* in the treatment of chronic urticaria generally. Lastly, the critical dissertation of Lœchner,<sup>12</sup> and the memoirs of Heberden,<sup>13</sup> and of Kock,<sup>14</sup> are worthy of being consulted.

CASE XXIII. *Indigestion in consequence of eating mussels; urticaria.* Madame N\*\*\*, twenty-eight years of age, of a sound constitution and in the enjoyment of good health, partook abundantly of mussels at breakfast on the 2d of February, 1820. A short time afterwards she experienced general uneasiness, a kind of anxiety about the precordia, and headache. Called to render my assistance, I found the tongue clean, the epigastrium the seat of an uneasy sense of weight, the abdomen natural and soft, the pulse slow and depressed, the respiration good, but somewhat oppressed; the whole surface of the body, and especially the lower limbs, were covered with numerous wheals or raised spots, of from half to a whole inch in diameter, of a paler colour than the skin, and affected with a sensation precisely similar to that which follows the stinging of nettles. These spots,

(a) The practitioner must not yield to the impatience for immediate relief sometimes manifested by those suffering under urticaria, and be led in consequence to prescribe the external application of cold or of saline washes. Fatal results have been brought on by these means.

which were evidently caused by partial swellings of the true skin, were surrounded by inflamed areolæ. (*Two grains of tartrate of antimony to be dissolved in three glasses of water, one to be taken at intervals of ten minutes.*) The patient vomited several undigested mussels, but many fewer than she had swallowed. She, however, felt greatly relieved. (*Emollient cataplasms to the abdomen, lavements.*) In the evening the wheals had disappeared, and the patient was better; next day she felt perfectly well.

CASE XXIV. *Urticaria, gastro-enteritic symptoms.* G\*\*\*, sixteen years of age, had complained for several days of headache, pain in the abdomen and loss of appetite. On the 25th of February, 1826, after eating rather less breakfast than usual, he went a short way into the country, but soon returned and lay down in bed. When brought to see him, he was complaining of an intolerable sense of heat over the skin, and particularly on the insides of the arms and thighs, and on the neck, which he compared to the stinging of nettles. These parts were in fact found on examination to be covered with large prominent spots or wheals, whiter than the skin which surrounded them, and precisely similar to those produced by urtication. Somewhat later, similar prominent spots appeared on the breast; these were surrounded by a highly inflamed areola. The patient had scratched himself severely, and to this perhaps the redness of the skin was owing. The face was a little puffed, the eyes sparkling and the head hot; farther, the tongue was white and stippled with red points; there was thirst, and pain and heat of the epigastric region; retching was induced by taking a little lemonade; the bowels had been locked up for two days; the urine was scanty and high-coloured; the breathing was unaffected (*sixteen leeches to the epigastrium; demulcent drinks sweetened with honey; cataplasms to the abdomen after the fall of the leeches.*) Next morning the eruption had entirely disappeared; the febrile symptoms and pain of the epigastrium were greatly relieved. Towards four o'clock in the afternoon, however, there occurred another paroxysm of fever, followed by a second eruption of nettle-rash, which in less than half an hour spread from the chin over the trunk and limbs (*twelve leeches to the epigastrium; drink as before; lavement*). Within an hour the eruption had gone away completely, and the patient felt relieved. He continued bathed in sweat during the night. Next morning, perfect apyrexia. There was no further return of the nettle-rash, and the gastric symptoms subsided by a few days attention to diet.

CASE XXV. *Acute urticaria returning at irregular intervals. Prescription of sulphate of quinia.* J. Lepommier, aged 47, in the enjoyment of good health, uninterrupted till within the last six months, was received into the hôpital St. Antoine, on the 7th September, 1829. On the 4th he had been thrown into a violent passion, and the same evening his skin became covered with wheals of nettle-rash, which were excessively itchy, and prevented him from sleeping. The night was very restless; in the morning every part of the body was covered with patches of urticaria, some of which were as large as the hand, others much smaller; all were surrounded by an erythematous areola. In several places, instead of the pale prominent wheals, broad red spots were observed, level with the general surface of the skin and irregular in their circumference. These disappeared completely under the pressure of the finger, whilst the redness around the wheal only became fainter. The pruritus continued, and came on in paroxysms; the pulse was full and frequent; the face and limbs were swollen and covered with true nodosities. The abdominal and thoracic viscera were unaffected—(*venes. ad 3xvi.*) The blood was buffed. 9th.—The heat and pruritus are less troublesome; the red areolæ are more conspicuous than the prominent wheals; bowels relaxed; pulse full and frequent. (*Mucilaginous drink; julep; venes. ad 3viii.*) 10th.—The blood no longer shows the buffy coat. The pruritus so troublesome as to have prevented sleep; bowels still relaxed, (*medicine as before; cold bath.*) 11th.—The patient felt comfortable in the bath; on returning to bed, several new patches came out and proved excessively itchy. Two or three times during the day fresh spots appeared, which vanished again within an hour or less. A fresh eruption has been observed to come out regularly every evening, which lasts several hours, and disturbs or completely prevents sleep. (12th.—At night; *eight grains of the sulphate of quinia at the end of the evening paroxysm; lavement.*) 13th.—A smaller number of spots

showed themselves on this than on preceding days; but the patient is restless, and suffers from heat of skin and pruritus. 14th.—A very small number only of wheals had appeared, and the patient scarcely complained either of heat or itching. (*Sulph. of quinia repeated.*) The eruption after this appeared no more, and the patient left the hospital on the 23d of September cured.

## ARTIFICIAL EXANTHEMATA.

279. Menuret<sup>1</sup> remarked that cloths whitened with *eau de javelle*<sup>2</sup> which had not been properly rinsed before being dried, gave rise to erythematous eruptions, of no great severity indeed, but yet sufficiently troublesome. Towards the decline of the epidemic cholera of 1832, I saw a considerable number of convalescents suffering from chronic erythematous inflammations following the application of mustard poultices. The *urtica urens* and *urtica dioica* are familiarly known to produce an eruption very similar in appearance to that which accompanies the *febris urticata*.

Odier<sup>3</sup> having applied the emplastrum ammoniaci cum hydrargyro of the London Pharmacopœia, to a species of wen, the application was followed two days afterwards by an erysipelas, accompanied with much swelling, which spread to the whole arm. The redness and swelling continued for several days, when violent fever set in attended with an eruption over the whole body of large red spots, intermingled with small pimples. Two bleedings, and the antiphlogistic regimen, put an end to these symptoms in the course of a week.

I once attended a man, fifty-nine years of age, labouring under a lumbago, who had an extensive erythematous eruption of the loins produced by frictions with the oil of the lauro-cerasus. This affection consisted of one large red blotch, not raised in any point above the level of the skin, but unevenly spread over the surface, which appeared stained and dotted in different places. This appearance was owing to the large red patch being formed by the agglomeration of many smaller ones, whose circumferences, less inflamed than their centres, melted away in different places into shades very little different from those of the healthy skin; several points of a more vivid red than the spots in general, scattered over their surface, gave to these last, and consequently to the large patch resulting from their conjunction, something of a dotted or stippled aspect.

The red colour disappeared momentarily under the pressure of the finger. The patient complained of slight pruritus in this part, but there was no morbid increase of temperature, nor any swelling of the subcutaneous cellular membrane. All the principal functions of the body were properly performed. The efflorescence was left to itself; the lumbago yielded to the use of gentle purgative glysters; the red patches of the loins finally grew pale, and were followed about the seventh day by a slight desquamation of the cuticle.

Amongst the numerous patients who are seen at the dispensary of La Charité, and who there take the vapour or the sulphur bath, I have seen many attacked with vesicular and papular eruptions, and with artificial exanthemata, which were always of short duration. Several other remedial means, such as ammoniacal or acid lotions, alkaline baths and sulphureous fumigations may produce artificial exanthemata, which are to be distinguished from each other, and from diseases depending on internal causes, by mounting to their sources.

M. N—, forty-six years of age, having at four o'clock in the morning taken forty-four grains of belladonna, was seized about an hour afterwards with supra-orbital headache of the most violent description, and excessive redness of the skin, which first appeared about the eyes and face, and then extended to the whole of the integuments. Within a few minutes the entire surface of the body presented a uniform red tint exactly similar to that observed in scarlatina; the throat of the patient was also intensely red, and affected with heat, which seemed to be propagated through the whole course of the alimentary canal. Another remarkable symptom was this: that the urinary passages, and especially the neck of the bladder, became extremely painful. The patient, in the midst of his delirium, was

<sup>1</sup> Recueil périod. de la soc. méd. de Paris, t. xxxiii. p. 43.

<sup>2</sup> A solution of the chlorate of potash in water.—R. W.

<sup>3</sup> Mém. de la soc. roy. de méd., t. iii. p. 213.

perpetually asking for the pot de chambre, and it was with difficulty that he succeeded each time in passing a few drops of red and bloody urine. All these distressing symptoms were relieved by a copious bleeding, demulcent drinks, soothing glysters, and the application of leeches.

Several other substances taken into the stomach, occasionally cause exanthematous eruptions. In a case of poisoning by the *Datura stramonium*, which occurred in a child two years old, Dr. Meigs, of Philadelphia,<sup>1</sup> tells us that the face of the patient became of a deeper scarlet colour than he had ever observed it, even in scarlatina; the skin was hot, the pulse very quick, the tongue and fauces dry and red; the tongue was so parched that its surface appeared shining. The face, the neck, and the breast, were covered by a multitude of small spots of a brilliant red colour, many of which were star-shaped.

## BULLÆ, OR BULLOUS INFLAMMATIONS.

Vocab. *Bulla. Phlyctena.*

280. Bullous inflammations of the skin are characterized when at their height, by small tumours, varying in size from that of a pea to that of a goose's egg, generally transparent, and formed by the effusion of a serous or sero-purulent fluid between the corion and cuticle.

281. Two cutaneous inflammatory affections constantly appear under this form: these are pemphigus and rupia. Ampullæ, or the vesications produced by violence, and that follow the application of blistering plasters, compose a group of artificial bullæ very distinct from the preceding. Bullæ are also accidentally developed in the course of many phlegmasiæ of the skin, and particularly in burns and frost-bite, in erysipelas, [small-pox, varicella] and several acute species of eczema.

282. Rupia was classed by Bateman among the *Vesicles*.<sup>2</sup> He says, "the eruption is characterized by broad and flattish vesicles." Vesicles and bullæ do not differ essentially from each other except in their size, and I greatly prefer classing rupia with the bullous inflammations, the disease having a much nearer affinity to pemphigus, and especially to pemphigus *infantil*is, than to scabies, miliaria and the other vesicular eruptions. When herpes zoster or zona, has attained its complete development, it very frequently appears with the characters of a *vesiculo-bullous* inflammation, which seems to form the link of connection between bullous and vesicular diseases. Willan assigned this disease its true place among the *herpetes*, and I committed an error when I removed it from that group in the first edition of this work.

283. An erythematous spot of one degree of intensity or another, probably always precedes the formation of bullæ, although this cannot in every case be demonstrated. The period of time required for the evolution of bullæ is very various; they may be formed almost instantaneously in one case, and in another advance with extreme slowness to their greatest height. The fluid they contain is most commonly serous and transparent, but occasionally it is sero-purulent or sanguineous; now and then it is separated from the dermis by an interposed layer of coagulable lymph; it may remain for a long time pent up in situations where the epidermis is thick and strong, as in the palms of the hands, soles of the feet, &c., or be speedily shed on the surface of the skin when the bullæ are thrown out on such parts as the eyelids, the cheeks, the lips, &c. This fluid often dries up and forms solid scabs of various thickness, and the skin, which these incrustations cover, either secretes a new epidermis and heals up rapidly, or becomes affected with ulceration, the cure of which proves more or less tedious.

284. The vesications produced by violence, by the application of cantharides, of liquor ammoniæ or boiling water to the skin, or by simple over-distension of the integuments, always indicate a degree

of local irritation greater than that which causes the erythematous blush; but it would nevertheless be impossible to demonstrate that the skin was more violently irritated in pemphigus and rupia than in scarlatina and urticaria. We cannot institute comparisons between the intensity of inflammations of different forms unless they are produced by the same cause. Thus the simple redness, the vesication, and the eschar, produced by a burn, are degrees of inflammation successively of greater intensity; but when causes come to be different, comparisons are no longer admissible; and we cannot say that the bleb of pemphigus is the index of a higher degree of positive inflammation than the efflorescence of scarlet fever, or the pustule of small-pox.

285. Bullous inflammations at their height cannot be confounded with any of the exanthemata. (209.) They have, on the contrary, great analogy with the vesicular inflammations, from which, however, they differ in the characteristic size of their vesications; bullæ being always much more considerable than vesiculæ. The *accidental* bullæ, produced by the confluence of several vesicles, such as are occasionally observed in zona and other varieties of herpes, present a peculiarity of character that always distinguishes them from true bullæ: their bases are constantly irregular, and seem composed of minute arcs of circles which proclaim the fusion of several smaller vesicles into one.

286. The diagnosis of these inflammatory affections, necessarily uncertain when the bullæ are not completely developed, or when the erythematous spots that precede the bullæ alone appear upon the skin, may also become very obscure when the bullæ are broken, their contents dried up, and they are succeeded by incrustations of variable thickness, by marks or by superficial sores or excoriations. The uncertainty can only then be dissipated by accurate information relative to the state of the skin previous to the formation of any scabs, marks or ulcers, or by a minute study of the form, the kind and the size of the alterations consequent on the different species of bullæ. (Vide Pemphigus, Rupia.)

## PEMPHIGUS.

Vocab. *Bulla, Hydatides, Pemphigus, Pemphigoid fever, Pompholix.*

287. Pemphigus is characterized by the eruption on several regions of the body of one or more large, yellowish and transparent bullæ, which terminate by the effusion of the fluid they contain, and the formation of a scab of variable thickness, or of a superficial excoriation.

The various appearances which the age of the patient (pemphigus *congenitus*, pemphigus *infantil*is), the number of bullæ (pemph. *solitarius*, pemph. *confluens*), their mode of appearing (pemph. *simultaneus*, pemph. *successivus*), the greater or less rapidity of their course (pemph. *acutus*, pemph. *chronicus*), the existence or absence of febrile systems (pemph. *pyreticus*, pemph. *apyreticus*), &c., give to this eruption, have been the cause of a multitude of distinctions, which pathologists have created to facilitate the study of the disease. I adopt, as fundamental distinctions, the two following: pemphigus *acutus*; pemphigus *chronicus*.

288. *Acute* pemphigus, (*febris bullosa, febris pemphigoides, febris synocha cum vesiculis*, &c.) is a rare disease. I have seen but a very few cases of it. It may be general or partial. It appears on every region of the body, most commonly on the lower extremities; occasionally, however, also, on the arms, the trunk and the face; it is very seldom seen on the soles of the feet, the hairy scalp or the genital organs. The bullæ almost always stand apart from each other.

The disease occasionally attacks without precursory symptoms; but may also be preceded by a sense of general uneasiness, violent pruritus of the skin, and slight fever; or otherwise it is ushered in by an irregular chilly fit, after which the skin becomes parched and burning, the patient complains of thirst and anorexia, and the pulse becomes excessively rapid. These symptoms last for one, two or three days. The eruption then shows itself by one or more circular or oval red spots, slightly prominent, and varying from a few lines to several inches in diameter. At first of a bright red, they soon turn to a more dusky hue. Their development is preceded and accompanied by pain and heat in the affected parts. The erythematous patches are

<sup>1</sup> North American Medical and Surgical Journal, January, 1827. Extract in Journ. des progrès des sciences et des institutions médicales, t. iii. p. 242.

<sup>2</sup> Bateman, Synopsis, &c. 5th ed. p. 243.

next transformed into true *bullæ* or *blebs*. A certain quantity of transparent serum, effused beneath the epidermis, raises it in the form of vesications which have with justice been compared to the blisters produced by the application of hot water or cantharides to the skin. The development of these bullæ often takes place almost immediately after the appearance of the erythematous blotches, the entire surface of which they rapidly cover; a circumstance which has led some writers to suppose that pemphigus was not preceded by any redness of the skin. The existence of these red patches, however, is so positive that bullæ occasionally appear surrounded by a distinct circular red border, which happens from the parts of those patches nearest the circumference, not being implicated in the bleb covering its centre and the greater portion of its superficies.

The skin between the bullæ appears perfectly unaffected; at least this is the case where the bullæ do not approach very closely to each other, for where they do it may present a more or less decided erythematous blush.

The number of bullæ is in general so much the greater as the disease attacks a greater extent of the integuments. Occasionally, however, a small number of bullæ have been seen disseminated over the entire surface of the body; whilst in other circumstances they have been observed thickly congregated in a single district. Now and then there exists no more than a single large bulla (*pompholyx solitarius*, Willan). The development of this bleb, which rapidly acquires such dimensions as at length to contain several ounces of serum, is preceded by a sense of smarting in the part where it is to appear. This bleb bursts in the course of eight and forty hours. It often happens that a second bulla arises two or three days afterwards in the vicinity of the first; and this may be followed in its turn by two or three voluminous bullæ which are evolved in the same manner; but the disease now generally becomes chronic in its nature. This variety is extremely rare. I have seen it occur on the leg of a young man convalescent from dothineritis.

The bullæ of pemphigus vary in size from that of a split pea or an almond to that of a hen's egg or a large blister. From the very moment of their formation the bullæ possess, in a great measure, the size they will attain at every subsequent period. Having reached their height, the greater number of them contain a serous fluid, which is transparent, and of a yellowish or yellowish-green colour, similar to the serum of an ordinary blister. When the primary inflammation of the skin is very acute, a quantity of coagulable lymph may be deposited on the outer surface of the dermis. Plump and distended during their growth and at their acme, which usually extends over a period of two or three days, the bullæ of pemphigus then become flaccid, wrinkled and half full; they form towards their most depending part a small hanging pouch in which the serum is mostly contained. At the end of from twenty-four to forty-eight hours the majority of them give way, and suffer the greater part of the fluid they contained to escape.

After the bursting of the bullæ, if the epidermis be detached by rubbing, or in any other manner, *excoriations* result; which are painful in a greater or less degree. Even more commonly, however, the bullæ are replaced by lamellar incrustations, which are of a pale brown colour at first, and become gradually of a deeper hue as they grow older. When these scabs are in their turn detached, the skin remains marked with spots of a dusky red hue in those places where the bullæ had been evolved. The duration of each bulla extends on an average to about seven days; that of acute pemphigus varies from one to two weeks when the eruption is *simultaneous*, and from three to four weeks when it is *consecutive*.

When the eruption of the bullæ is simultaneous and confluent, or when pemphigus is complicated with another inflammatory affection of the skin, it is almost always attended by a febrile paroxysm; if the eruption invades the mouth or the genito-urinary organs, if it be combined with a deranged or inflamed state of the digestive apparatus, or of any other important organ of the body, the general symptoms may assume a character of considerable intensity. An acute pemphigus, accompanied by a copious eruption, has been observed to produce delirium, extreme restlessness, and exhaustion in children, and in old persons to be followed by adynamic symptoms of such gravity, as in some cases to have even proved fatal.

We occasionally observe bullæ imperfectly developed. These appear under the form of circular and prominent erythematous patches. By passing the finger over their surface, the cuticle is felt to be loosened, and a slight effusion is perceived between it and the dermis. The loose portion of cuticle is detached at the end of a few days, and leaves exposed a red spot covered with a thin and glistening epidermic layer.

289. *Chronic pemphigus (maladie vesiculaire, dartre phlyctenoides confluent, Alibert; pompholyx diutinus, Willan)*, is a much more common disease than acute pemphigus, from which it differs in the long continuance of the eruption, which commonly extends over several months, by the mode of development of the bullæ, which is always successive, and by the absence of febrile reaction, at least during the earlier periods of the disease.

290. Chronic pemphigus especially attacks men advanced in years; occasionally, however, those in the prime of life suffer from it; individuals of the male are much more frequently attacked than those of the female sex. The bullæ of chronic pemphigus succeed each other at various intervals during from ten weeks to seven or eight months, and occasionally, even during several years. In one case they are confined to a single region, in another they invade every part of the body in succession. Several days before the first eruption of the bullæ patients commonly complain of pains in the limbs, and feelings of lassitude and depression; these sensations, however, are often so slight as to be passed over without attracting particular notice. Small *red patches*, preceded by smarting, show themselves on one or several regions of the body, from the centres of which the epidermis begins to rise whilst their circumference spreads, so that in the course of a few hours bullæ are formed as large as filberts or even as walnuts, and by the end of two or three days, several acquire the size of a pigeon's egg. These bullæ are either burst from being rubbed, or give way in consequence of mere distension. The raised portion of cuticle then sinks down and becomes wrinkled or lies in folds over the surface of the inflamed dermis; or if it be removed completely, painful excoriations are left bare and unprotected, in the immediate neighbourhood of which the epidermis looks wrinkled, and subsequently undergoes a slight exfoliation. The bullæ which have not been broken become turbid and sink down; they assume a whitish colour, and by and by are replaced by flattened scabs, of little thickness and of a brownish hue. New bullæ continue to arise in the neighbourhood of the old ones, and are sometimes preceded by prickling or smarting sensations, a febrile paroxysm, and violent lancinating pains, similar to those which herald the eruption of shingles; I have heard several patients compare the pains they suffered to the impression of the electric spark.

Such are the appearance and the most usual progress of chronic pemphigus; but they may be variously modified.

The usual antecedent circular red patches, for example, are occasionally not visible except on the evolution of the first bullæ, or otherwise, only before the last crops of the eruption that happen. I have in several instances seen the bullæ begin as vesicles no larger than lentils, which afterwards went on increasing till they attained the size of small eggs. Some bullæ are surrounded by an areola, others are not. Most commonly disseminated and distinct, bullæ are more rarely seen clustered together in irregular groups, or arranged in rings similar to those of two varieties of herpes.

Bullæ may be confluent or conjoined by their bases; in this case they are soon seen to contain purulent matter, and are succeeded by thin scabs, the intervals between them being occupied by squamæ that lie in some degree over one another. This variety is most commonly seen on the face. Occasionally the eruption fixes on a small surface, three or four inches in diameter; I have, however, seen it more frequently confined to the face, hands and forearms on which bullæ continued to follow each other during several months; the affection has also been seen on the lower part of the leg. When the eruption is considerable the patient is sometimes obliged to keep his bed; but there is rarely any degree of fever present, unless, indeed, the inflammation have been propagated to the mucous membranes. When the excoriations are numerous, patients often sink exhausted by pain and want of rest, or are cut off by dropsical affections and colliquative diarrhæas.

221. Pemphigus affecting the skin may be preceded or accompanied by an inflammation the same kind of the mucous membranes of the alimentary canal or genito-urinary apparatus. This affection either shows itself under the form of circular red patches, or of flattened bullæ on those parts that are provided with an epithelium. I had an opportunity of observing this extension of the disease to the mucous membranes, to a very great degree, in an old mayor of Paris, labouring under chronic pemphigus complicated with prurigo, whom I attended along with Messrs. Maury and Kapeler. On several different occasions we could perceive flattened bullæ on the lining membrane of the mouth and pendulous velum of the palate, and in the last stages of the disease, which the most unwearied attention had no influence in checking, the inflammation extended to the great intestines, the bladder and bronchiæ.

Inflammation of the mucous membrane of the mouth and fauces is often seen allied with pemphigus of the face, of which disease, indeed, it is then a mere extension. Cæco-colitis, cystitis, and inflammation of the vagina frequently complicate the disease when it appears on the parietes of the abdomen, or on the upper and fore parts of the thighs. In these complicated cases, the functional disorders of the digestive organs and of the urinary passages are associated with the morbid phenomena induced by the inflammatory affection of the skin. The appearance of the bullæ is preceded or accompanied by a state of languor and lassitude, by headache, sickness, dysuria, pains in the limbs, &c. Besides the gastric and intestinal disorders, which complicate pemphigus so frequently that they have even been regarded by M. Gilibert as one of its elements, other affections, and particularly several forms of skin disease, such as herpes and prurigo, are occasionally added to the list. Pemphigus may also occur in the course of vaccinia and scabies; and it has sometimes appeared to decide the fate of internal inflammations, such as pneumonia and dysentery, and to replace rheumatic attacks. But M. Gilibert was, in my opinion, deceived when he regarded erysipelatous inflammations, presenting accidental phlyctenæ here and there, as instances of this exanthematous disease, complicated with pemphigus. It is also necessary to be on our guard against confounding true pemphigus with the accidental bullæ which are observed to occur in some old cases of scabies, or in consequence of œdema. Those writers have also done wrong, as I conceive, who have contrasted with acute pemphigus those usually flaccid phlyctenæ half full of bloody serum, which occasionally appear on the buttocks and trochanters in the course of severe dothineritic affections.

222. *Structural Changes.*—The alteration of the skin that occurs in pemphigus, is precisely similar to that which results from the second degree of burning, and the application of blistering plasters. In pemphigus infantilis, the dermis is often ulcerated in the centres of the bullæ (Case XXVIII). The mucous membranes of the nipple, of the vulva, of the lips and inside of the mouth, are all frequently the seat of true bullæ. It was a mistake to suppose, as has been done, that the bullæ of pemphigus could be evolved on the mucous membrane of the stomach and intestines, these parts not being provided with any epithelium; but it is certain that in chronic cases of pemphigus which have terminated fatally, the redness, thickening, softening, ulceration, and other changes induced by inflammation in mucous membranes, have frequently been encountered. The greasy liver has several times been found in individuals who have died from pemphigus.

223. *Causes.*—These are in general very obscure. Pemphigus appears more particularly during the autumn and winter; it attacks both sexes, and individuals of every age, but especially old men. It has also been seen as a congenital affection. The serous fluid of its bullæ has been inoculated, but the punctures did not inflame. M. Garde and I tried the experiment on ourselves, performing the operation with purulent serum from the bullæ of a woman advanced in years, and affected with chronic pemphigus, but without other effects than such as follow a simple puncture. The process of dentition among infants; excesses or irregularity in diet, and violent moral affections among adults; and amenorrhœa and dysmenorrhœa among women, have all occasionally seemed to influence the development of pemphigus. Several authors have observed the disease as an epidemic.

Chronic pemphigus attacks those individuals especially whose

general constitutions have suffered; living in cold and damp places, and on unwholesome food, seems also to favour its development, which, under other circumstances, is perfectly inexplicable. The blood is often found to be buffy during the continuance of the disease.

224. *Diagnosis.*—When the bullæ are distinct and unbroken, pemphigus cannot be mistaken for any other disease. In an anatomical point of view, burns, attended with vesications, have some resemblance to partial pemphigus, but the cause that produced the blisters enables us to distinguish the two affections. When a single bulla (*pompholyx solitarius*) constitutes the whole affection, and appears without an areola, it resembles in all respects the vesication produced by a blistering plaster, and the one does not in fact differ from the other, save in the exciting cause. I shall by and by have to relate a case of pemphigus simulated by means of the powder of cantharides. In rupia, the bullæ, which are usually less numerous, smaller and flatter than those of pemphigus, are followed by true ulceration of the skin, and become covered at length with thick and prominent scabs.

The bullæ which we find now and then accidentally developed in erysipelas, differ from those of pemphigus by appearing on an extensive surface of a uniform red colour, with swelling of the subcutaneous cellular substance.

When the bullæ of pemphigus are small and clustered together, (Case XXX,) the eruption may be distinguished from herpes phlyctenodes, by the circumstance of the bullæ of pemphigus being always larger than the vesicles of the herpes, as well as by the former being uniformly accompanied by isolated blebs that sufficiently proclaim the nature of the general affection.

The scabs of pemphigus are distinguished from those of impetigo by being thinner, less rugous, and shagreen like; they are also generally bulging in the middles, wrinkled in their circumferences, and formed of a single piece that represents the extent and something of the form of the bullæ to which they have succeeded. The scabs of acute pemphigus frequently present a perfectly characteristic disposition: the incrustation formed by the drying up of the fluid collected in the most depending parts of the bleb, is covered by a cuticular disc of a yellowish-brown colour, and of the size of the bullæ.

The marks which pemphigus leaves after the detachment of the scabs or cuticular discs, are separated from each other by healthy skin, of a dusky red colour; they are of various magnitudes, and often bounded in their circumference by a very distinct epidermic border.

225. *Prognosis.*—Acute pemphigus without pyrexia, ends naturally within two or three weeks. When the eruption is preceded, attended, or followed by febrile symptoms, the disease assumes a character of gravity, great in proportion as it is complicated with nervous and adynamic symptoms; this last complication is happily very rarely met with.

Chronic pemphigus indicates a bad state of constitution; it is always a very obstinate affection, and proves troublesome in the same ratio as it is more extensive, more frequently renewed, or complicated with chronic bronchitis, inflammation of the bladder, &c. Pemphigus pruriginosus often proves fatal when it attacks persons in the decline of life.

Several cases are related in which pemphigus seemed to have a beneficial influence on the course of some internal maladies. I once saw a man who, after having had several attacks of hæmoptysis, became subject to chronic pemphigus of the legs, and from this period the bleeding from the lungs did not recur. The cure of pemphigus has, in some cases, been observed to be followed by various ill consequences.

226. *Treatment.*—In acute pemphigus without fever, when the bullæ are few in number, and not of very large dimensions, the eruption may be left to itself, or at most, the serum of the vesications should be evacuated by one or two small punctures made in the epidermis.

When the eruption in this form of the disease is more considerable, care is to be taken that the cuticle continues applied to the surface of the spots that have sustained bullæ; these are sedulously to be protected from friction, and in case they should become denuded, are to be immediately dressed with a perforated rag (*linge fenêtré*) spread with cerate. The general treatment may consist in the exhibition of diluents,—lemonade, and the vegetable acids,—milk diet, the antiphlogistic regimen and an occasional warm bath. Should the erup-

tion have been accompanied or preceded by fever, or the inflammation of any internal organ, should the patient be of a robust constitution, or the bullæ have followed amenorrhœa, bleeding from the arm or foot must be practised, or leeches applied in the vicinity of the part affected.

When chronic pemphigus implicates but a small extent of surface, and the state of the constitution appears satisfactory, the disease will occasionally yield to the use of diluents, and of the warm or cold bath, either simple, or alternately with a tepid slightly alkaline bath, which is found greatly to relieve the accompanying pruritus and heat of the skin.

In an adult, or one whose constitution does not appear to be sensibly deteriorated, should chronic pemphigus have invaded through a period of several months, almost the entire surface of the body successively, should there be at the same time fever, and numerous excoriations scattered over the skin, and should the inflammation, in fine, have spread to the mucous membrane of any part, a general bleeding ought by all means to be practised, whilst the skin is covered with emollient gelatinous or oily applications.

Emollient baths are often of service, but they must not be continued too long, nor taken at too high a temperature. When the patient is too weak to use the bath himself, this means must be abandoned, as painful excoriations are almost constantly produced by giving him any assistance out or in, or by helping him into his bed. In such circumstances the patient must be laid on an oil-cloth whilst the inflamed parts of the skin are covered by compresses, frequently renewed, wrung out of some emollient and narcotic decoction.

Lastly, when the accompanying inflammatory affections of the stomach and bowels become very severe, and when blood-letting cannot be had recourse to on account of the weakness and state of exhaustion of the constitution, we turn to soothing and narcotic medicines, especially to such as contain neither wine nor alcohol, in graduated doses. When sickness or pain of stomach is excited by a draught of fluid, the drink may be administered by spoonfuls at a time to quench the thirst.

Occasionally recourse has been had, with success, to a milk diet, which was subsequently changed by degrees for more nutritious food. In elderly persons, whose constitution did not appear to have suffered materially, and when there were no symptoms of irritation in the digestive organs, the acidulated decoction of bark, wine and water, bitters, chalybeate medicines, and a tonic regimen have all been found of advantage; the mucous membrane of the digestive apparatus, however, so seldom escapes implication in this variety of pemphigus, that too much caution cannot be observed in the use of these medicines and remedial means.

When the digestive apparatus is healthy, purgatives are sometimes beneficial. Sherbets prepared with the nitric and sulphuric acids continued for several months, have also effected remarkable cures.

Chalybeates, such as the subcarbonate of iron, in doses of half a drachm or two scruples, the sulphuret and carburet of iron, the vinum ferri, &c., are all very serviceable when the eruption has been preceded by dysmenorrhœa and amenorrhœa.

The preparations of arsenic are always to be prescribed with great discretion, and only when the stomach and intestines appear perfectly free from actual disorder, (Case XXX,) or from predisposition to inflammation.

Pemphigoid inflammations of the mucous membranes occurring in old subjects where they have continued long, or been frequently revived, ought not to be treated by the detraction of blood, which only reduces the strength, without preventing the return of fresh eruptions. Soothing gargles, and such as are acidulated with the muriatic acid, or prepared with a solution of alum, often produce favourable modifications in bullous inflammations of the mouth and pharynx. Diuretic drinks containing a portion of nitre, and emollient topical applications to the pubes, along with glysters of pellitory, often relieve the dysuria and check the hæmaturia that occasionally supervenes during the last stages of chronic pemphigus. The diarrhœa, which often precedes these symptoms, as well as the sleeplessness occasioned by the pain of the excoriations, and the accidental occurrence of prurigo are to be soothed by opium in one form or another. When the continued action of opium seemed to oppress the stomach, I have frequently, and with good effect, ordered half, or three-quarters of a grain, of the

hydrochlorate of morphia to be applied to the abraded surfaces of one or more of the bullæ. Dropsical symptoms occurring at this period are almost always the precursors of approaching dissolution; the scene of pain and suffering, however, is more frequently terminated by an obscure affection of the lungs.

#### Historical Notices, and particular Cases of the Disease.

297. The account which Hippocrates<sup>1</sup> has left us of the *pemphigoid fever* is very obscure. Ch. Lepois<sup>2</sup> was the first who gave a clear description of pemphigus.

A great many observations have been published on *acute pemphigus*, in which the *eruption of bullæ took place at once*,<sup>3</sup> and on *acute pemphigus with successive eruptions*,<sup>4</sup> on *acute pemphigus complicated with intestinal*, or as they are styled, *biliary affections*,<sup>5</sup> with *gastro-enteritis*,<sup>6</sup> with *pneumonia*,<sup>7</sup> with symptoms of great depression,<sup>8</sup> with *vaccinia*,<sup>9</sup> and with *prurigo*.<sup>10</sup>

We possess a still larger mass of information in regard to *chronic pemphigus*,<sup>11</sup> to *hereditary pemphigus*,<sup>12</sup> and to the disease as it attacks the *aged*,<sup>13</sup> we have also some remarks on the disease with a *gangrenous* character,<sup>14</sup> which, perhaps, are rather applicable to *rupia escharotica* than to this complaint, on the pemphigus of *camps*,<sup>15</sup> on the complication of pemphigus with *hysteria*,<sup>16</sup> on the pemphigus of children,<sup>17</sup> of the *fœtus*, and of the *new-born infant*,<sup>18</sup> of *pregnant women*,<sup>19</sup> lastly, we possess the researches of M. Brachet<sup>20</sup> on several different species of pemphigus. The facts collected by M. Ozanam<sup>21</sup> on epidemic pemphigus, and the critical and historical inquiries of M. Bidault de Villers,<sup>22</sup> will all be perused with interest.

298. The following cases refer to several varieties of pemphigus. One of these is so rare as to have led many pathologists to question its existence; this is *pemphigus acutus*; another had never been

<sup>15</sup> F. Thierry states that, in 1736, there reigned at Prague a contagious and very fatal disease among the soldiers. The bullæ that rose upon the skin were as large as a hazelnut, and were very similar to the phlyctenæ caused by blisters (Médecine expérimentale, p. 134, 12mo. Paris, 1755). Langhans, under the title of pemphigus *Helveticus*, has described a disease that reigned in Switzerland in 1752 (Acta. Helvet., vol. ii. p. 260). It is difficult to say whether these epidemics ought to be considered as a severe species of acute pemphigus which does not now occur, or referred to a dothineritic affection with eruption of bullæ on the skin, a disease of which I have met with several cases.

noticed until I described it, pemphigus *circinnatus*; a third, pemphigus *infantil*, differs so essentially from the other varieties of the disease, that Bateman, who has pointed out its characters but very imperfectly, was led to look upon it as a species of rupia. The others, also, have all some remarkable peculiarity to distinguish them.

CASE XXVI. *Acute pemphigus, with simultaneous eruption of bullæ on the right forearm; annular erythema; herpes phlyctenodes.* A. B., twenty-three years of age and unmarried, had menstruated regularly since she was twelve years old. Had come to Paris three weeks ago, and entered the service of a restaurateur, where she had better food at her disposal than she had hitherto been accustomed to. No cause of moral nature appeared to have exerted any influence on the development of the disease for which she sought relief. Five days before entering the hôpital St. Antoine this young woman felt such a sensation of itchiness in the lower part of the right forearm, and in the hand of the same side, as would have led her to scratch the parts violently, had she not resisted the impulse. A number of small red spots appeared on the parts mentioned, during the existence of which the pruritus continued. These were succeeded by small blebs which gradually became larger and increased in number. The patient having now observed several red spots of a similar kind on different parts of the body, sought admission to the hospital on the 21st of August. The right forearm and hand were both found evidently swollen, and considerably hotter than the same parts of the opposite extremity; they presented several red points of a very small size, numerous bullæ, excoriations, incrustations, whitish spots that had been covered with scabs, and a few vesicles.

The fingers alone exhibited any of the red spots mentioned; they were not numerous, pretty regularly rounded, of the size of a small lentil, and disappeared momentarily under pressure; bullæ varying in size from that of a pea to that of a hazelnut were scattered over the lower part, and especially the inner surface of the forearm; they were pretty closely crowded together; from twenty-five to thirty could be counted in a space scarcely so large as the hand. They were generally very regular in their shapes, and as large at first as they became at any subsequent period; some few, however, evidently, increased by the extension of their circumference. Those which were irregular in their outline, were so evidently in consequence of being formed by the fusion of several bullæ together, which, thus conjoined, assumed the form of the figure 8, or appeared like a string of beads. They were almost all without areolæ; some, however, were surrounded by a very conspicuous border. Through several of the most transparent bullæ the rosy colour of the cutis vera could be perceived. The want of transparency in others seemed to be owing to the formation of a very thin layer of whitish matter on the surface of the corion. The oldest bullæ had become perfectly opaque either in consequence of the formation of pus, or of the great thickness of the false membrane they contained.

There were but a very few excoriated places consequent on the abrasion of the cuticle. Here and there a few incrustations and cuticular laminae, proceeding from the drying up of the blebs, were conspicuous. All of these adhered strongly to the skin; several consisted in fact of nothing but a circular lamina of cuticle, which, after having been soaked with the yellowish serum or purulent fluid of the bullæ, sank down on its evacuation and became applied anew to the surface of the corion. These circular laminae, usually of a yellowish-brown colour, were continuous with the healthy cuticle at their circumference. Others of the scabs were more complicated in their structure, and consisted, besides the cuticle, of a true, yellowish, rounded scab, half the size of the superposed cuticular lamina itself, and here occupying its centre, there one of its segments. These laminae and scabs were generally thrown off in a single piece, and exposed the last traces of the disease, which consisted in rounded and not very numerous marks of the same size as the crusts that had been detached, and of a dull white colour, which formed a marked contrast with the natural rosy tint of the skin. A few crusts of the kind now described, existed on the fore part of the trunk. Besides these various organic changes, which were all proper to pemphigus, an erythematous patch was perceived in the form of an oval circlet perfectly regular in its outline, the centre being occupied by healthy skin. This ring was not covered by any vesicle.

The skin covering the lower halves of several of the metacarpal bones, and first phalanges of the finger, was beset by a great number of vesicles, the size of a small pin's head, or of a split pea, here and there isolated, but in general congregated into irregular clusters. Several of these were surrounded by a border of a deep red colour. The general health of the patient was good. She was put upon diluents and spare diet,—lemonade and the quarter hospital allowance.

23d.—Several bullæ which last evening were distinct had become joined by their edges and now communicated with each other; a circumstance of which we were assured by making a puncture into one of them, and letting out the fluid which the whole that were so united contained. 24th.—The bullæ were all broken and covered either with the shrunk and wrinkled cuticle, or the peculiar incrustations of which mention has been made above. 29th.—No new bullæ had been developed. 30th.—A few marks, some of a dusky hue, from which the incrustations had been forcibly removed by the patient, others of a dull white, from which the scabs had fallen off of themselves, were now the only traces of the disease remaining. The patient had three-quarters of the hospital allowance, took a warm bath, and on the third of September left the hospital cured, although the circular marks on the forearm still proclaimed the nature of the affection under which she had laboured.

CASE XXVII. *Chronic pemphigus; bullæ arranged in bands; complication with herpes circinnatus;* Grainprot, sixty-eight years of age, entered the hôpital St. Antoine on the 13th of August, 1828; of a naturally good constitution, this man had been living in the country during the last two months, and was habitually employed in gardening. In the month of June, 1827, when the heat was excessive, he states that he had the first attack of a disease similar to that under which he now labours, and from which he then recovered completely in five weeks. In the same month of the present year (June, 1828,) a new eruption of bullæ showed itself, first on the wrist, and subsequently on other regions of the body. On the 15th of August they presented the following characters on the right arm: 1st, prominent red spots of various forms; 2d, bullæ in different degrees of development; 3d, incrustations; and 4th, certain alterations that did not appear to be owing to the pemphigus.

The spots were flat on the surface and of a deep red colour; they varied from the size of a split pea to that of a shilling; they were slightly raised above the level of the surrounding skin, and disappeared for an instant when pressed on by the finger. They were distinct in several parts of the extremity, crowded together in others, and occasionally ranged one after the other, so as to resemble in some sort irregular curved bands of different breadths, some being but a few lines and others much more across. The red borders, with which these bands were furnished, terminated sharply in the healthy skin on the convex aspects, but on their concave edges they were gradually diffused and lost in the areola with which the bands were on this side surrounded. This arrangement, however, was not universal; and the bands in various places included patches of apparently healthy integuments within their concavity. The red patches generally, were sensibly hotter than the neighbouring parts, and at a subsequent period became covered with bullæ.

The disposition of the bullæ corresponded in general with that of the red spots and bands; in other instances they surrounded the incrustations about to be mentioned, and then they were much more minute. They varied in size from that of a split pea to that of a hazelnut. Some of the bullæ were transparent; but in general, they were opalescent; almost all contained limpid serum and a false membrane of a dirty white colour, occasionally tinged with infiltrated blood, an appearance which was conspicuous in even the most recently formed bullæ.

The greater number of the bullæ were full and tense; others of older date were shriveled, and looked as if a part of the fluid they contained had been absorbed.

If the bullæ were opened, their contents evacuated, and the false membrane, generally included, detached, the surface of the corion appeared of a rose colour similar to that of the primary patches on which the bullæ were themselves evolved.

The scabs or incrustations, of the same dimensions as the bullæ to which they had succeeded, were like these, now isolated and distinct,

now congregated in stripes. They were of various hues, from a yellow to a deepish brown, adherent to the skin, of considerable thickness in their centre, but much thinner towards their circumference, where they were squamous and consisted of the cuticle alone. If they were detached, the red surface of the corion was exposed, generally dry, but now and then smeared over with a little sero-purulent matter.

Besides, the organic alterations, now described, proper to the disease that immediately occupies us, a number of perfectly transparent vesicles of the size of large pins' heads existed on the right arm, mingled with the bullæ of the pemphigus. A large phlyzaceous pustule with a hard and red base, the centre of which was covered by a brownish scab, was also developed on the outer aspect of the forearm near the elbow joint.

The *left arm* also exhibited the eruption of pemphigus in all its stages; and here the stripes or bands sometimes appeared completely annular, including circular portions of healthy skin; this appearance was even more frequent on several parts of the body. The bullæ on this as on the opposite extremity were very numerous, and although completely transparent, included almost universally a false membrane, which, in the older ones, either presented spots of a dull white, or the sanguinolent infiltration of which mention has been made.

It was on the right lower limb that the elevated red bands were most completely beset with bullæ. One of these bands pursued the following course: from the level and vicinity of the trochanter major, it passed obliquely inwards towards the scrotum; turning back, it descended along the thigh to the fore part of the knee, which it surrounded in an imperfect manner; it then mounted, winding as it advanced along the outer aspect of the thigh, till it attained the point from which we have traced it as commencing. This long band was made up of several smaller ones, which represented arcs of circles of various diameters. The area which this band circumscribed was occupied by healthy skin, beset here and there with red patches covered with blebs and vesicles. It was in the course of this great band so particularly described that the largest bullæ of the pemphigoid affection were encountered; so that this belt of bullæ bore the most striking analogy to the groups of herpes *circinnatus* which existed on the other thigh and especially on the trunk.

The bullæ were more numerous on this extremity than anywhere else. Attacked more recently, it exhibited none of the incrustations described as existing on the arm, but it presented a new feature not observed elsewhere, namely a number of *excoriations*, the dimensions of which varied between that of a sovereign and a double sovereign piece. They were all superficial, the corion being destroyed in no one of them.

The *left leg* exhibited no bullæ, but in different places it presented several circular red bands which completely circumscribed portions, greater or less in extent, of healthy skin; the diameters of these varied between that of a silver two-penny piece and that of a shilling. These rings were almost all covered with transparent vesicles the size of large pins' heads or small lentils (*herpes circinnatus*).

The herpetic groups, well characterized in the region I have just mentioned, were still more so on the trunk. One was seated below the left breast, four on the epigastric, and many more on the hypogastric region; they were, however, more numerous on the back than anywhere else. Three groups in this region placed one over the other, and joined by their edges, formed an elevated band between two and three inches in length, by six or eight lines in breadth, which presented three different circular patches of healthy skin; the centre of one of these groups was occupied by a crust of ecthyma, more prominent than the red line by which it was surrounded; a boil of considerable size was observed in the centre of a cluster situated over the right scapula.

The pemphigus at length also appeared on the upper part of the throat and on the chin; here the blebs were less regular; the serum they contained became more speedily turbid; and the scabs were thicker, and longer of drying than in other situations. Further, the hair-follicles of these regions inflamed and poured out a thick matter of a yellowish-green colour, which concreted into crusts, like those of impetigo. The other parts of the face, and the hairy scalp continued free from eruption.

All the parts affected were hot, and troublesome sensations of itchiness and smarting were complained of, especially in those points that, within a few hours afterwards, became covered with an eruption of blebs. These symptoms were so much the more violent as the eruption proved copious, or was actually confluent; they were scarcely felt in the right arm, which was the part first affected.

The general state of the patient was rather satisfactory; the thorax and abdomen were not affected; the intellect alone seemed weakened, and the patient had long been in a state verging on fatuity. (*Lemonade for drink, gum julep, and broths and soups for diet, were ordered; and the excoriated parts were dressed with simple cerate.*)

During the few first days Grainprot remained in the hospital, new bullæ were successively thrown out, especially on the legs and trunk; but they always appeared upon prominent red blotches, which, isolated at first, soon united into the raised bands I have mentioned, and changed their shape. On the 20th, bread, gruel and vegetables were added to the diet, and a few cups of herb-broth (*bouillon aux herbes*) were taken during the course of the day. By the 22d, the original elevated bands which presented themselves the preceding days on the right thigh, were no longer visible. But new blebs, thrown out on spots prominent like the others, and assuming the same arrangement in bands, made their appearance on the left thigh. The circular clusters increased in number on the dorsal region, which here and there presented bullæ, mixed with vesicles evolved on the spots themselves. The patient complained of having had two loose motions the preceding evening.

The red spots were more numerous than ever on the 23d; on the inner side of the thigh an immense bleb, nearly as large as a crown-piece, its base surrounded by a red border which was well defined and distinct from the healthy skin in its neighbourhood, made its appearance. *A grain of tartrate of antimony was now added to the lemonade, and the quantity of food formerly allowed was diminished by one half.*

On the 25th, the erythematous rings, and round vesicular groups, were so greatly increased in number that the primary form of the inflammatory affection was masked. On the dorsal region, however, several circular clusters were still visible, which, uniting together, composed various figures, among which, many of the figure 8 were very distinct. The diarrhoea had increased; the patient had lost flesh since his entrance into the hospital, and during the last two days, the pulse had become quick: the prognosis was less and less favourable. On this day the patient was induced to leave the hospital, and it is with regret I have to state, that no further information could be obtained as to the issue of the serious disease under which he laboured.

It is worthy of remark that this patient had been for two years successively affected with pemphigus; on each occasion, too, during the hottest months of the year, and that it was only on the second attack that the eruption became general.

CASE XXVIII. *Chronic Pemphigus presenting isolated bullæ, and clusters of an eruption similar to that of herpes phlyctenodes; amenorrhœa; recovery.* Frances Richard, 42 years of age, and of a good natural constitution, had for some years past been subject to slight but frequent indispositions. The menstrual discharge had been almost always irregular and scanty; she was married at about twenty-two, and had had three children, who all died young. For fourteen years she had laboured under profuse leucorrhœa, the consequence of a clap. About five months ago, on the return of a menstrual period, she had a shivering fit, which lasted several hours, and was followed by febrile symptoms. Two days afterwards leeches were applied to the thighs; the menses did not recur, and an eruption of bullæ, which appeared singly and in groups, came out successively on the thighs and trunk, and on the fronts and insides of the arms. The pruritus was excessive, and was increased by the warmth of the bed. The patient was brought to the hôpital St. Louis, where she remained during several weeks under treatment, by means of baths of the decoction of bran, lemonade and sulphur pastiles. She left the house without benefit, passed some time at her own home, and obtained admission into the hôpital de la Charité on the 6th of March, 1833.

The upper extremities, especially the forearms, on their inner and anterior aspects, are covered with irregular groups of round, convex, semi-transparent bullæ, the size of a pea, or larger, filled with a thin

and limpid fluid, separated from each other by very small spaces, in which the skin looks red and injected; in some places the bullæ join each other by their edges. Here and there, especially on the upper lip, inner aspect of the thighs, and lower part of the lumbar region, a few isolated bullæ are to be seen. The bases of these isolated bullæ are here sharply circumscribed by the healthy skin, there surrounded by a red circle, which is visible about all that occur in clusters. When the serum is evacuated and the cuticle is removed, the subjacent dermis appears reddish, granular, moist, and but little inflamed. The patient having acquired the habit of pricking the blebs as soon as they appear, very few have been allowed to run their natural course, yet here and there scabs, formed by their contents, become dry, are to be met with; these crusts are of rather a lightish brown colour; they are prominent, slightly conical, granular, unequal at their bases, and adhere pretty firmly to the skin, which appears either slightly excoriated, or merely red. In other places the crusts are thinner and plain, or only very slightly convex; to conclude, no other traces of bullæ remain in some places than a few slight epidermic exfoliations of a circular shape, adhering by one of their edges and covering reddish or brownish spots; these spots are most numerous above the right buttock.

The bullæ always appear in successive crops, and the patient has fancied that she could perceive the skin of the places where they were about to appear to become redder than natural, and to be affected with considerable pruritus; each bulla rapidly attains its largest dimensions; the itching is especially troublesome when the body becomes heated, by being warmly covered in bed, for example.

The skin of the front and inner parts of the forearms, no point of which has escaped being the seat of bullæ at one time or another, appears to be thicker than natural. The principal functions of the body, respiration, digestion, and circulation are performed with perfect regularity; but the patient has had no return of the menstrual flux for several months. (*Barley water, with half a drachm of nitric acid; carbonate of iron, in doses of twenty-four grains.*) The bowels had been constipated, but were relieved by two cold glysters.

March 9th.—Several bullæ on the forearm were touched with a solution of nitrate of silver; sharp smarting pains during the day; eruption of new bullæ to which the caustic solution was also applied. 10th and subsequent day.—The same medicines were continued; great numbers of bullæ appeared around the parts that were cauterized. On the 20th the use of the warm bath was begun, and regularly continued every day till the 1st of April, at which date the dose of the carbonate of iron had been carried the length of thirty-six grains daily.

The thighs now presented but a few isolated bullæ; the daily eruption on the forearms, though it still took place, was much less in amount than formerly. Alkaline baths were prescribed, each containing four ounces of carbonate of potash; of these the patient took six in the course of eight days, but without any great benefit from their use.

On the 8th the menses appeared for the first time during the last five months and flowed but scantily for two days. On the 12th, without any evident or known cause, the patient was affected with febrile symptoms for which blood-letting was deemed necessary and prescribed, although it was not practised; by the 14th the fever had very much abated. The skin complaint now showed a great change; the bullæ were no longer transparent, but were filled with a sero-purulent fluid; the skin of the forearms was greatly flushed, and the itchiness had given way to a sense of smarting. The patient took seven gelatinous baths, and internally a cup of decoction of endive, with the addition of two drachms of sulphate of soda occasionally. On the 21st the patient was much better, and no new eruption of blebs had occurred. Half a drachm of the solution of arseniate of soda<sup>1</sup> was now prescribed, and the dose afterwards carried to a drachm. The patient bore the medicine well; no new bullæ appeared, and the skin showed no symptoms of inflammation. The cuticle on the forearms began to be thrown off. On or about the first of May, a cluster of very small bullæ was observed in the bend of the arm; these contained but a very small quantity of serum, and disappeared at the end of a few days, without being followed by any more. The same medicine

continued. On the 8th the menstrual discharge set in and proved more copious and lasted longer than it had done for several years.—On the 15th the patient was discharged, and promised to return should her disease recur. She still continued well on the 15th of July.

CASE XXIX. *Pemphigus infantilis; ulceration of the skin; gastro-intestinal inflammation.* P. Francoise, weakly in constitution, seven months old, and already weaned three, was brought by the mother for advice on the 7th of July, 1828. Six weeks previously the infant had had an attack of ophthalmia, which got well without any treatment, and was speedily followed by a very remarkable disease of the skin, which appeared successfully on the chin and neck, and on the fore and back parts of the body. The different appearances that characterize it seem to form parts of the same malady, which, according to the mother's account, showed itself almost simultaneously on the different parts now affected, and without being preceded by any peculiar symptoms.

This eruption consists of round bullæ in different stages of red excoriations, circular in form, humid, and almost uniformly ulcerated in their centres, and of a few scabs which present peculiar characters.

1. The bullæ are pretty regularly round, the size of a large lentil, almost always distinct, and scattered over the surface of the trunk, but here and there congregated into irregular groups, especially upon the back, when they are surrounded by an areola, which disappears with pressure. The fluid of the bullæ is opalescent and escapes when the cuticle is removed. The surface of the corion where exposed looks red, and the centres of the spots are almost always occupied by a small grayish-coloured ulcer, much inferior in extent to the excoriation itself. This small central ulcer, which might be covered with the head of a pin, corresponds to a point of the skin which is softened and infiltrated with a drop of purulent matter.—These hemispherical bullæ with the ulcerated centres, had already lasted several days when they were examined.

2. The excoriations consecutive to the bullæ, when deprived of their cuticular covering, almost all present a central ulcer, which is generally larger and deeper than in the bullæ just laid open. When the bullæ have been crowded, these remaining sores have occasionally spread into each other and formed small ulcerated bands, very analogous in appearance to those met with in some forms of syphilitic skin disease. The ulcers are of various depths, some penetrating through the whole thickness, others implicating no more than the superficies of the corion; they are uniformly surrounded by red areolæ.

3. A few incrustations are observed here and there, between the bullæ and the ulcerated parts. They look about the size of the original bullæ, are yellowish in colour, of no great thickness, and adhere to the skin; some of them have a slight depression in their centre of a lighter yellow, and corresponding to the seat of the little ulcer of which mention has been made. All the parts affected appeared to be very painful.

Besides the skin complaint, the belly of the child has, according to report, been tense and voluminous for several weeks past; the tongue is slightly red, and there is rather a profuse diarrhœa. *The sore places were dressed with fine linen spread with cerate, and protected with soft lint; demulcent drinks were ordered, light nourishment in smaller quantity than usual, and emollient baths.*

13th July.—New bullæ have arisen; several are of very recent date, and appear opalescent, not in consequence of the nature of their fluid contents, but from enclosing an opaque false membrane of a yellowish-white colour. When this exudation was removed, the papillary surface of the dermis looks as in the older bullæ, of an uniform red colour, but the centre instead of a true ulcer, only presents a small whitish spot, which, however, marks the point that at a later period was to become the seat of ulcerative absorption.—The bowel-complaint had ceased. *Same treatment.*

15th.—No new bullæ have been developed, but many of the old ones still continue; the skin, indeed, over the scapulæ and lower part of the left side of the thorax, is almost of one uniform red tint from the conjunction of the areolæ that surround each of them or the consequent excoriation. These parts seemed also to be very painful. Four leeches were applied to a portion of healthy skin that occupied

<sup>1</sup> This solution is the *liqueur de Pearson* of the French. It consists of one grain of the arseniate of soda, in one ounce of water.—R. W.

nearly the centre of a group on the left shoulder-blade, and the former dressings and demulcent drinks were continued.

20th.—The little patient appeared greatly better; there were now no more than three groups of ulcers on the lower parts of the chest. The scabs that have been detached from the single bullæ have left small isolated and depressed cicatrices; those that have followed the ulcerated bands are tortuous and irregular, and seen, for the first time, might very readily be ascribed to a very different cause than that to which they are due. By the 24th of July there were no symptoms remaining of the bullous inflammation with which the infant had been affected; but on this day new signs of gastro-intestinal irritation were exhibited; these, however, were successfully subdued by means of a warm bath and other soothing remedies.

CASE XXX. *Chronic pemphigus of both legs, recovery under the use of arsenical preparations; subsequent insanity.* M\*\*\*, nearly fifty years of age, was very ill in April, 1827. He then had sinapisms applied to his legs, which caused considerable inflammation, followed by some discharge, which continued for nearly two months. M\*\*\* had occasion to travel to the south, and about the month of October, the legs, especially the calves, were attacked with chronic pemphigus, characterized by the eruption of bullæ six or eight lines in diameter. Baths and emollient poultices, saturnine and sulphureous washes, were employed one after the other, without success. On returning to Paris on the 1st February, 1828, I was consulted. I found the disease principally seated in the posterior, outer, and fore parts of the right leg; every point, however, was not affected in the same manner, nor in the same degree. I remarked, 1st, rounded, reddish eminences, the size of a French bean, which were painful and firm to the touch, and looked like flattened tubercles; these elevations were the eruption in its first stage. Next day the eminences were changed into true bullæ, filled with transparent serum. 2d. Several bullæ, here at their height, round, and distended with transparent serum, there sunk down and flaccid, or ruptured, and empty. 3d. Flat, laminated and yellowish scabs proceeding from the drying up of the bullæ. 4th. Red and bleeding excoriations, some circular like the distinct bullæ; others of different forms and broader, consequent on the junction of several contiguous bullæ. Some of these excoriations had the appearance of recently blistered surfaces, others that of a blistered part covered with a white or shriveled membrane. 5th. Between these different morbid changes, the skin was reddish in some places, and in others preserved its natural appearance. The inflamed parts were not very hot; the pain only came on in paroxysms, and was excited by any attempt at walking, which, indeed, was nearly impossible; the patient consequently kept his room. He called my attention to the circumstance that the painful paroxysms came on principally during the night, and that each new eruption of bullæ was preceded by violent pains in the calves. Speaking of the pain he endured, M\*\*\* expressed himself nearly in the same terms as individuals use who are affected with bad shingles. The right leg was swelled, and infiltrated inferiorly. On the left leg alterations of a similar kind, but much less violent in their character, were apparent.

The digestive organs were unaffected; the bowels, however, were obstinately constipated, occasionally for four or five days at a time, despite the repeated use of lavements. The kidneys performed their office perfectly; there was nothing amiss with the functions of respiration and circulation. The nervous system alone seemed affected. M\*\*\* was excitable, very irritable, contentious, and eccentric; he also occasionally complained of a sense of heaviness in the head.

I directed the legs to be dressed with pledgets spread with saturnine cerate, and covered with soft lint, as if they had been affected with vesications after a scald. At each dressing the lint was carefully detached after being well wetted with decoction of althea; every other day the patient took a gelatinous bath, and each day he drank a considerable allowance of veal broth. Under this treatment, which was continued for nearly three weeks, several bullæ dried up and were replaced by others; the patient was alternately better and worse. Almost regularly after coming out of the bath, the legs became more distended, and after this afflux there was an evolution of one or several bullæ: the patient consequently soon went into the bath with reluctance, as the skin only seemed to become more tender under its influence. A blister had already been applied to the arm, and I now put

the patient on the use of phosphate of soda, and then of calomel in purgative doses, but without deriving any benefit from the measure. Twenty leeches were next applied to the right leg, and this step was attended with more harm than good, the bites becoming inflamed, and suppurating without any sensible amelioration in the state of the affected parts.

The obstinacy of the disease, and the good state of the digestive organs made me resolve on trying the solution of arseniate of soda, and the patient was put upon doses of this preparation, successively increased from six to eight, ten, fifteen, twenty-five, and thirty drops. There was a manifest improvement from the time that the doses of twenty drops were attained. The legs were completely cured at the end of a month, under the influence of the medicine, which, however, was continued for a fortnight longer. Besides its effects upon the disease, this medicine caused some slight derangement of the digestive functions, but not to the extent of colic, or diarrhœa, or vomiting; it also induced a slight puffy state of the countenance, with several erythematous blotches on the fingers. These inconveniences ceased of themselves on the use of the remedy being discontinued.

At a later period this patient, who for a long time back had been observed to be *very eccentric*, was attacked with mania. After several bleedings had been practised without doing any good, M. Esquirol and I agreed to try the effect of a succession of blisters upon the parts that had been affected with pemphigus. These applications made no impression on the disease of the brain, which degenerated into dementia, and two years afterwards the patient died paralytic.

#### RUPIA.

Vocab. *Rupia, Ulcers-atic.*

299. *Rupia* is characterized by small isolated, flattened bullæ, filled with a serous fluid which soon becomes opaque, puriform, or sanguinolent, and to which succeed black, thick, and prominent scabs, whose bases conceal ulcers of variable depths. Three varieties are observed: *rupia simplex*, *rupia prominens*, and *rupia escharotica*.

300. *Symptoms.*—*Rupia simplex* is commonly evolved on the legs, sometimes on the loins and thighs, and more rarely on the other regions of the body. It is proclaimed by one or more flattened bullæ about the size of a shilling, which at first contain a serous and transparent fluid. This fluid, however, soon becomes turbid and purulent, it then grows consistent, and is finally transformed into scabs of a chocolate colour, thicker in their centres than around their circumferences, their outer layer being continuous with the epidermis, which appears detached by the serum or pus in which their edges are bathed. Under these scabs, which are detached naturally within a few days, or are accidentally rubbed off, the true skin is found to be excoriated. This superficial sore, left to itself, either heals up, or is covered with another scab, which falls off at a later period, and this process may be repeated several times successively. After cicatrization is accomplished, the skin retains for a very long time a livid, deep red colour.

In *rupia prominens* the bullæ are larger, the succeeding scabs thicker and the consequent ulcers deeper. Each bleb is preceded by a circular red spot, over which the cuticle is slowly raised by a blackish-looking, thick fluid, which soon concretes, and gives occasion to the formation of a scab, whose thickness and size increase for some days afterwards. The circumference of this incrustation is surrounded by a reddish border a few lines in breadth, the epidermis of which is raised by a fresh effusion of serous fluid, that forms a new incrustation, and adds to the extent of the one originally produced. The areola also spreads slowly around the base of the scab first formed, which itself increases in breadth and thickness during three or four, and sometimes even during seven or eight days. The scab then appears very broad in comparison with its thickness, and is often very aptly likened to an oyster shell. More commonly, however, the incrustation projects in the same degree as it spreads, becomes conical, and bears the greatest resemblance to the shell of the limpet. The scab of *rupia* generally adheres firmly, and can only be detached with the assistance of moist and emollient applications. The skin once exposed, appears ulcerated to an extent and depth that vary in

every instance. If the part affected remain exposed to the air, a new crust is either formed after a greater or shorter interval, or the ulcerative process extends more deeply, and spreads till it sometimes approaches the size of a crown-piece in breadth; the sore in this case looks pale, and bleeds readily. These ulcers, which are usually characterized as *atonic*, and the cure of which is only obtained with extreme slowness, are always succeeded by cicatrices, subject to break open afresh, the brownish livid hue of which continues for a very long time unchanged.

3. *Rupia escharotica* is evolved more especially in cachectic infants, and occasionally in elderly persons, or in adults who have suffered from chronic rheumatism, or constitutional syphilis; it is most usually seen upon the legs, the thighs, the scrotum, the abdomen, the loins, the neck, the upper part of the chest, and but very rarely on any part of the upper extremities. It begins by one or two red and livid spots, over which the cuticle is soon raised by the effusion under it of a serous or sero-sanguinolent fluid. These bullæ go on increasing in an irregular manner; the serum they contain becomes turbid, and acquires a blackish colour. By and by they give way, and the dermis, left naked, appears ulcerated, softened or gangrenous in different points; a bloody and very offensive sanies bathes the surface of the sore, the edges of which are livid and not very painful. In adults I have seen *rupia escharotica* acquire the dimensions of *rupia prominens*, and small portions of the skin and cellular substance, stricken with sphacelus, become detached slowly from the surface of the ulcerated parts. In children the bullæ of *rupia escharotica* do not generally acquire so large a size, but they follow each other in greater numbers; the succeeding sores become very painful, cause fever and sleeplessness, and may exhaust the patient in the space of two or three weeks. In every case the cicatrization of these sores is a very tardy process, and is always expected long before it happens. Ecthyma is a form of cutaneous disease that is often seen along with *rupia simplex*, but very rarely with *rupia escharotica*. I have seen many cases of *rupia* complicated with purpura and with chronic rheumatism, as also in individuals labouring under constitutional syphilis.

301. *Causes*.—Scrofulous children, and the offspring of the poor, of delicate constitution, or who have been weakened by previous illness, are predisposed to *rupia*. The disease shows itself particularly during the winter season among such as are insufficiently clothed, badly lodged and ill fed, more especially after any other form of inflammation of the skin, such as variola, scarlatina, measles, &c. I have seen *rupia*, as just stated (300), complicated with purpura hemorrhagica. The disease also frequently appears among the aged, though those in the vigour of life are by no means exempt from it.

302. *Diagnosis*.—The small flattened bullæ of *rupia* very commonly contain a turbid serous fluid. They cannot be mistaken for the large transparent and prominent blebs of pemphigus. Besides, the rough, thick, and often prominent scabs of *rupia*, and its succeeding ulcers, are very different and easily distinguishable from the laminated incrustations and superficial excoriations of pemphigus. Yet the pemphigus *infantil*, in which the skin often appears ulcerated in the centres of the blebs, seems in some sort to form the link of connection between these two diseases. *Rupia* differs from ecthyma in its primary form, which is bullous, whilst that of ecthyma is pustular; the base of the pustules of ecthyma is much inflamed, and the scabs, with which they become covered at a later stage of their progress, are hard, and, as it were set, or encased within the substance of the skin; the circumference of the bullæ of *rupia* does not present the same degree of inflammation, and their incrustations are much broader, more prominent, and less adherent than those of ecthyma. It must be allowed, however, that the bullæ of *rupia* become purulent very quickly, and that occasionally the diagnosis is rendered so much the more difficult, as the two eruptions are met with at one time in the same individual. Nevertheless, the prominent incrustations, and the deep, and often intractable ulcers of *rupia* are very different from the impacted scabs and slighter sores of ecthyma. It does not seem possible that *rupia escharotica* can ever be confounded either with anthracosis, which is surrounded with a broad erysipelatous base, or with frost-bite of the hands and feet presenting bullæ and gangrenous spots.

303. *Prognosis*.—*Rupia* is never a dangerous disease; the *escharotica* species itself is only serious when the eruption is very abundant.

When the disease appears on the legs it is always succeeded by intractable ulcers. The duration of the disease cannot be precisely calculated, but depends greatly on the age of the patient, the number and size of the bullæ, on the consequent sores, the degree in which the general constitution is affected, and the influence which certain concomitant maladies, such as scrofula, and chronic affections of the lungs and alimentary canal, may exert on its progress.

304. *Treatment*.—The treatment of *rupia* is of a general and local nature. The object proposed by the first is to bring about a modification of the constitution acting faultily in a greater or less degree. The milk of a good nurse for infants at the breast, exhausted by hunger, and in misery, through want of proper care; a nutritious meat diet—beef or mutton, and generous wine mixed with water for children and adults of lax fibre and a scrofulous habit; a regimen adapted to any form of concomitant disease, if the general health has suffered,—such, in a general way, ought to be held the objects of primary and highest importance. (a)

The local treatment may be as follows:

The bullæ of *rupia simplex* are to be opened if they contain serum, and the parts covered with a soft rag and some lint, the dressings being kept in their places by proper bandages.

After the fall of the scabs in *rupia simplex* and *rupia prominens*, the ulcerated skin is to be bathed with decoction of althea if it be painful; but if the inflammation appear indolent and below the pitch requisite for the production of a new epidermis, or the formation of a cicatrix, it may be stimulated with a wash of wine and water, or a weak solution of cream of tartar. I have been in the habit of ordering the sores of *rupia* to be dusted with cream of tartar, and of all the topical applications I have tried, this is the one that seemed to me to answer best. (b)

Rest, the horizontal posture of the body and limbs, and continued gentle pressure, assist the cicatrization of the ulcers. Sticking plasters may be employed in some cases where the legs are affected, and the blebs are isolated or few in number; but whenever the round shape of the ulcers is modified, it is proper to change the adhesive straps for a perforated rag and a compress of lint, maintained by a proper bandage. If the adhesive plasters be continued too long, the parts almost always grow livid and fungous, a state that requires the repeated application of escharotics. The best of these, when they do become necessary, is the nitrate of silver, and the use of this is often followed by good effects. In some cases the nitric or muriatic acid, or the acid nitrate of mercury may be advantageously employed.

When the eruption extends to several regions of the body it will be necessary to resort to alkaline and sulphureous baths of regulated strength, alternating these with the simple warm bath.

To cleanse the skin and get rid of the incrustations, as also to enable us the better to ascertain the state of the excoriations, I make it almost a general rule to order a warm bath for the patients we receive into our hospitals. For scrofulous subjects a sulphureous bath is usually substituted, and this is had recourse to again from time to time during the treatment.

#### Historical Notices and particular Cases.

305. There are but few individual cases of *rupia* recorded; yet the disease is perhaps more common than pemphigus. If it appear less familiarly known to practitioners, it is because the bullæ that characterize it are always few in number, and soon replaced by scabs and excoriations which have been described by many surgeons as *atonic* or *incrustated* ulcers, &c. Willan and Bateman were the first who gave a good account of this disease; Lorry seems to have seen it.<sup>1</sup> A case

(a) Mercury has been advised in some cases; but it ought to be prescribed, if at all, as an alterative and not sialagogue.

(b) Ointments of the protiodide of mercury (a scruple to the ounce, and of the biniodide of mercury 12 or 15 grs. to the ounce) have been strongly recommended by Bielt. Mr. Wilson succeeded in an obstinate case with a strong solution of alum injected beneath the edges of the bullæ.

<sup>1</sup> "Horret sæpè cutis crustis superpositis, et rupium ad instar sese mutuo excipientibus" (Lorry. De morb. cut., p. 81). Vid. p. 76: Nasci purtulas illicò cruore plenas, etc.

has been quoted by one writer which was aggravated by the use of mercury.<sup>1</sup>

CASE XXX. *Rupia of the legs in a child.* I attended a child belonging to poor parents, eight years old, of a fair and pale complexion, and lymphatic and scrofulous habit, in whom three flattened bullæ, each the size of a six-penny piece, filled with bloody serum and surrounded by an inflamed areola, were evolved on the lower and outer part of the right leg. Two other bullæ having similar characters, were also observed on the same region of the left leg. These bullæ, which had been evolved within four and twenty hours, burst on the day I was called, and were completely emptied of their contents. The day after, each of the bullæ was replaced by a thin brown scab which adhered to the skin. (*Hopsea; bullæ dressed with saturnine cerate spread on a perforated rag: fomentations with elderflower water.*) I saw the child eight or ten days afterwards. In this interval the incrustations had been repeatedly detached along with the stockings of the little patient. The dressings had not been regularly applied, and the scabs were always reproduced. I now recommended the incrustations to be got off by means of a soft poultice, the parts that were inflamed and deprived of cuticle to be covered with a pierced rag, spread with saturnine cerate, a little soft lint, and a firm bandage above all. Within a fortnight the child got well, but the skin long retained a deep purple hue in those points where the bullæ had appeared.

CASE XXXI. *Rupia of the legs, ecthyma and petechiæ, œdema of the feet, use of the supertartrate of potash.* In the month of May, 1823, I had a water-carrier under my care for an ecthyma, the large pustules of which had principally appeared on the thighs. This man, who was in his sixty-sixth year, was pale and emaciated, and had a worn-out appearance. Ill clothed, ill lodged and ill fed, he was often exposed to cold and moisture; he had suffered several attacks of bronchitis, and repeatedly laboured under diarrhœa. When I saw him, however, for the second time on the 2d of July, 1823, he showed no signs of either gastric or pulmonary affection. He applied to me on account of three flattened bullæ, having a large and but slightly inflamed base, which had appeared on the lower and outer part of the left leg. Two days afterwards the blebs had changed into brownish incrustations, which increased in thickness for some time afterwards. Besides the bullæ six or seven petechiæ were observed, and a small ecchymosed spot on the leg, near its articulation with the foot, which was œdematous. Having no expectation that cicatrization would go on readily under the scabs, I recommended them to be removed by means of an emollient poultice, and the superficial excoriations they covered to be then dressed with a piece of linen pierced with holes, a compress of soft lint, and a firm retaining roller above all, extending from the ends of the toes to the middle of the leg. The dressings were not regularly attended to, and the patient continued to ply his ordinary occupation so long as his strength would permit him. The two excoriations became painful, bled frequently and began to spread; a month was passed in this way. The patient at last consented to lay himself up. He was supplied with wholesome food; the leg was kept in the horizontal posture during a part of the day at least; the sore places were stimulated by being powdered with cream of tartar; a firm bandage was applied and regularly changed. Three weeks had hardly passed before the œdema of the foot, the petechiæ and the ecchymoses had disappeared, and the excoriations were replaced by two livid cicatrices. A laced stocking was subsequently put on instead of the roller.

CASE XXXII. *Rupia escharotica.* A woman twenty years of age, of a lax constitution, presented herself among the out-patients at the hôpital St. Antoine, on the 22d of June, 1828, having an eschar, a little larger in size than a shilling, on the inner part of the left leg, around which the skin was a good deal inflamed, tense, shining, painful and swollen. This eschar had been preceded some days before by a large bleb, which had burst, and been succeeded by a black scab. The disease was evidently a case of isolated gangrenous rupia. *Compresses wet with cold decoction of althea during the day; emollient poultices through the night.* 24th. The eschar began to be detached from the inflamed skin in its circumference; the surrounding redness

was greatly less. 2d of July.—The eschar was detached, and the destructive process perceived not to have implicated the entire thickness of the skin in every part of the sore. Rest, and a few applications of powdered cream of tartar, caused the rapid cicatrization of the ulcer, which in this instance proved to be of a more purely local nature than rupia is in general.

CASE XXXIII. *Rupia; recovery, followed by febrile symptoms, relieved by blood-letting.* Morreau, twenty-two years of age and of a bad constitution, was admitted into La Charité on the 24th of December, 1832. When I saw him first he had been some days under treatment for a rupia, the bullæ of which had already disappeared, and been succeeded by incrustations of a brownish hue, mixed with rather prominent yellow lines. In two points of the outer and lower surface of the right leg, the removal of these scabs had exposed as many oval-shaped ulcers about four lines in breadth, by nearly six in length: these sores were of no great depth, and of a pale reddish colour.

The treatment after the 1st of January, was changed from emollients to dressings with a perforated rag and soft lint; and subsequently the sores were touched with a solution of nitrate of silver. This plan, aided by the use of sulphurous baths, hastened the cicatrization of the ulcers, which was almost accomplished by the 20th. Till this time the general health had been good; but now, without any appreciable cause, beyond the drying up of his sores, the patient was attacked with irregular shivering fits, which continued the whole day long. On the evening of the 20th, heat of surface, and a general uneasiness, wandering pains of the lower part of the chest, headache, and frequency and force of pulse were superadded. The nights of the 20th and 21st were passed without sleep. On the visit of the 21st the face was flushed, though the headache was less severe; but the sense of constriction about the chest was as violent as ever; at one time crepitation was supposed to have been heard at the base of the right lung, but further examination did not confirm the suspicion. The patient had a little cough, and the chest sounded well on percussion; he had no expectoration whatever. The tongue was moist and natural; the epigastrium and rest of the abdomen were not painful on pressure. The patient had had a motion the preceding evening; the pulse was full, bounding and frequent; the skin hot and the thirst considerable (*barley-water, low diet, venes. ad 3xii*). Evening of the 21st.—Headache less; other symptoms the same; 22d, the patient had slept for two hours and was better (*the same treatment continued*). In the evening there was a marked exacerbation. These febrile symptoms continued till the 24th, after which they declined considerably; the patient felt his appetite returning, and on the 26th he was so far recovered as to be allowed some solid food. On the 28th the patient was dismissed, cured. The ulcers of the rupia were completely cicatrized, but the skin that covered them still retained a livid or blue colour.

#### ARTIFICIAL OR ACCIDENTAL EULLOUS INFLAMMATIONS.

306. Under this head I arrange vesications, blisters and other watery blebs, produced by local and evident causes.

#### AMPULLÆ OR VESICATIONS.

Vocab. *Ampulla, Blister, Vesication.*

307. This title has been given to the blisters which arise on the hands and feet, in consequence of violent and long-continued pressure, rubbing, pinching, &c. These blisters are preceded by redness, and heat and painful swelling of the skin; a serous fluid is then effused under the cuticle, which becomes raised in the shape of a rounded bleb of variable size, the sense of touch in the part being very much obscured or altogether destroyed.

When ampullæ are the consequence of pressure, violently and suddenly applied, as when a finger is squeezed between two hard bodies, they are evolved almost instantaneously; the fluid they contain is then tinged with blood, and their colour is of various shades of red. The

<sup>1</sup> Plumbe (Sam.). A pract. treat. on diseases of the skin, 8vo., Lond. 1824, p. 156.

whole of the thick and unyielding cuticle of the heel is sometimes seen raised in one large and uneven blister, which, indeed, is only perceived by the lookers-on from the more regularly rounded figure and greater size of the part than naturally belong to it; to the patient their existence is always sufficiently indicated by the tensive and acute pain they occasion.

Left to themselves, blisters of the hands and feet disappear slowly, the serum they contain is either absorbed, or escapes by a natural rent or an artificial opening made in the cuticle. The spontaneous rupture of blisters of the heel is always very long of happening; their fluid contents become brown and exceedingly fetid, and at last flows out by small openings in the thickened, macerated and partly destroyed epidermis.

308. Blisters of the hands and feet are only liable to be confounded with those that follow burns and frost bite. To distinguish them it is enough to mount to the cause which has produced them, when their situation is not of itself a sufficient index of their origin.

309. The best mode of treating ampullæ is to prick them in several places as soon as they are formed, and thus to evacuate the serum they contain; when they are very large, it is even better to lay them open through their whole extent. When this practice is not followed in regard to blisters of the heel, they are apt to be followed by small fistulæ, from which a very fetid ichor oozes out. In this case it is necessary to remove the flap of cuticle which is detached, to apply an emollient poultice upon the exposed surface, and then to cover the whole heel with a compress, wetted with a solution of acetate of lead. The inflammation subsides in a few days and a new cuticle is produced.

## BLISTER.

310. The name of blister has been especially given to the large bullæ, now commonly produced in the practice of medicine, by the application of cantharides to the skin. This form of inflammation is so usually looked on as a *remedy*, that some may be surprised to find me here speaking of it as a *disease*. The study of blisters, in a pathological point of view, however, appears to me a subject of so much the more importance as they occasionally give rise to serious consequences.

311. The formation of the vesication of a blister is rapid in the same proportion as the irritating matter employed is more energetic in its action. The serum effused between the cutis and cuticle is of a pale straw or citrine colour, and transparent: it has sometimes, however, though rarely, the consistence and appearance of a kind of yellowish jelly. After having by a small opening evacuated the serum of a blister completely, if the epidermis be pressed accurately down, it will by next day appear to be incorporated again with the general integument, and a new cuticle will be formed under the old one, which is detached at a later period. If, on the contrary, the cuticle be removed from the blistered surface entirely, the contact of the air with the inflamed skin causes pain of so severe a kind that it is often compared to the sensation produced by a scald. After the rupture of the bullæ the skin appears injected, and covered with small red points, which probably correspond with the papillæ. When the exposed surface of the skin is systematically irritated, or a blister is kept open, the part often becomes covered with a whitish-looking *false membrane*, which cannot be removed without causing the flow of some drops of blood, and to which a cicatrix, or a new cuticle would speedily ensue, did not renewed irritation cause the formation of pus. The false membrane which is here formed is composed of fibrin like those of the serous surfaces, but it differs from these inasmuch as no traces of organization have ever been detected in it. When the skin has been long kept in a state of inflammation, it bleeds often and readily, and occasionally becomes covered with exuberant fleshy growths or granulations in the form of tubercles separated from each other by fissures. These growths are owing to a true hypertrophy of the papillæ of the skin.

Blisters may also *ulcerate* in several points of their surface: a patient at La Charité, whose forearms were paralyzed in consequence of repeated attacks of lead-colic, was treated successfully by gradually

increased doses of strychnine applied upon two blistered surfaces on the dorsal aspects of the forearms; these blisters, however, were not long of becoming painful, and then exhibited several small ulcers which appeared to implicate almost the whole thickness of the corion. I have often since made use of the strychnine in the same manner, but have not seen any similar consequence ensue.

When the ulcers have not implicated the entire thickness of the dermis, the cicatrices that follow them have a pitted appearance which recalls the natural disposition of its parts when minutely examined.

Blisters have a livid appearance and bleed readily in some serious diseases. They also occasionally become gangrenous.

The pigmentum, the sebaceous follicles, the hair-bulbs, and the hairs themselves, sometimes become unnaturally developed in consequence of the application of blisters.

Blisters often cause troublesome pruritus, pain, and sleeplessness, especially in children. They may also give rise to painful inflammation of the lymphatic glands of the axilla, neck and groin, when they are applied to the arm, nape of the neck, or thigh. The inflammation in these instances even extends to the neighbouring regions and to the subcutaneous cellular substance. Blisters of a very large size are almost always followed by some degree of febrile reaction; like burns they may excite inflammation of the digestive organs, irritation of the brain and nervous system, &c.; their application in acute diseases is almost always followed by a temporary increase in the severity of the symptoms. M. Richard has seen an intermittent fever brought on by a blister, each paroxysm being preceded by acute pain in the inflamed portion of skin. I have myself seen the same thing: having ordered the application of a blister to the forearms of a man labouring under paralysis from lead, the pain and inflammation of the skin produced a violent paroxysm of fever which was even accompanied by fainting.

Corvisart thought that the secretion from blistered surfaces might be so profuse as to exhaust the strength of some patients; the same remark has been made in reference to the discharge from extensive burns.

512. The bullæ produced by the application of blistering plasters may be distinguished by the special nature of their cause from those that follow burns and frost-bite, or that are characteristic of pemphigus. Independently of other circumstances derived from their form, situation and extent, blisters in a suppurating state, or dried up and covered with scales, differ in their mode of formation from the superficial ulcerations or excoriations, and circumscribed squamous patches which follow certain bullous and vesicular inflammations.

When blisters have been long kept open, or when they have had good effects, whether on the constitution at large, or on the progress of a local affection, they are of the number of those inflammations which it is dangerous to suppress on a sudden. Notwithstanding this, however, when the disease which induced their application is cured, if it be not *constitutional*, *hereditary*, or liable to *return*, it is proper to bring about the cicatrization of the secreting surface by dressing it either with some soothing cerate, or simply by abstaining from irritating it longer. If the intestinal canal be healthy, one or several successive doses of purgative medicine are then generally prescribed with great propriety.

Excessive growths from blistered surfaces are to be kept down by the application of some escharotic, or removed entirely with curved scissors.

Sulphureous baths hasten the absorption of the pigmentary marks produced by blisters.

*Historical Notices and particular Cases.*

313. Blisters have of late been studied in an anatomical point of view by M. Villermé<sup>1</sup> and by M. Gendrin;<sup>2</sup> Messrs. Brandes and Reimann have analyzed the fluid of the vesications;<sup>3</sup> and Broussais has satisfactorily proved that blisters employed as revellents in chronic affections of the stomach are more frequently noxious than

<sup>1</sup> Villermé. Art. fausse membrane, Dic. des sc. médicales.

<sup>2</sup> Gendrin. Hist. anat. des inflammations, t. i. p. 416, in-8. Paris, 1826.

beneficial.<sup>1</sup> They may also cause ill effects in a greater or less degree under a great variety of other circumstances.

The powder of cantharides applied to the skin with a view to feign disease, may prove a cause of error in diagnosis. See Case XXXVI.

CASE XXXIV. *Intermittent fever produced by a blister*: (Richard, in the *Annales de la Médecine Physiologique*, tom. iii.) M. X\*\*\*, an officer of light troops, came under my care for wandering pains of the chest, dependent, apparently, on the fatigue induced by severe riding. There was no symptom of any considerable affection of the thoracic viscera; and the accession of a slight catarrh alone induced the patient to enter himself on the sick list. Regulated diet and demulcent drinks were employed for some time, but these not having answered the expectations of the patient, a few leeches first, and then a blister were applied to the left arm. On my return, after an absence of three days, I learned that M. X\*\*\* had every day suffered a rather violent attack of fever regularly at the same hour on each accession: I learned further that the discharge from the blister appearing insufficient to the dresser, he had taken it on him to stimulate the part by the application of fresh cantharides, and that the violent pain which followed this measure was the prelude to the febrile paroxysm.—Having no doubt of the irritation produced by the blister being the cause of the fever, I directed the application of a poultice moistened with laudanum, to the suppurating surface, and from this time the pain ceased, and the fever did not return.

CASE XXXV. *Eczema of the arm produced by a blister*. M. Ch.\*\*\*, aged thirty-two, of a sanguineous temperament, had been subject during several years, to a chronic coryza, which gave rise to an habitual and very copious discharge of a serous and mucous fluid from the nostrils. This flux was continual; so that M. Ch.\*\*\*, when he was engaged in writing, was often obliged to keep a handkerchief under his nose to catch the fluid that distilled from it. When this flux, which appeared in the first instance to have been brought on by the habitual use of snuff, happened accidentally to be suppressed, M. Ch.\*\*\*, who at other times enjoyed good health, was immediately taken with aching and a sense of weight in the head, symptoms which immediately disappeared on the return of the morbid secretion. After having tried various remedies for this inconvenient malady, M. Ch.\*\*\* resolved on applying a blister to his arm; this rose perfectly, and began to suppurate as usual on the two following days.

Several days afterwards, M. Ch.\*\*\* requested me to call on him and examine an eruption that had appeared around the blister, and caused so violent a pruritus that he found it impossible to resist scratching the parts. The inflammation extended over almost the whole anterior and outer parts of the arm. It consisted of vesicles and superficial excoriations; of the vesicles but few had escaped laceration; they were very minute, scarcely visible to the naked eye, and bathed by an abundance of yellow-coloured serum which exuded from the denuded skin. The excoriations had the precise characters of acute and ulcerated eczema,—a red uneven surface, with minute drops of blood scattered over it, and small distinct circular red points corresponding to the ruptured vesicles. The blistered surface was hot, bleeding and painful (*crum of bread poultice, with decoction of althea; cooling and emollient washes; warm bath; antiphlogistic regimen*). In spite of this treatment the eczema spread on the following days as high as the bend of the arm. The itching was intolerable. The secretion from the nose still continuing, I healed up the blister a fortnight after its establishment. The eczema, however, still continued for twenty days longer, at which period a slight redness of the skin was all that indicated its previous existence. A seton having been inserted into the neck, the flux from the nose was arrested.

CASE XXXVI. *Pemphigus simulated by the application of powder of cantharides*. Frances Bouillot, aged fifty-nine, was received into the hôpital St. Antoine, on the 6th of April, 1828, complaining of frequent fits of vomiting, pain of the epigastrium, and habitual constipation. She was put on the regimen pursued in cases of gastro-intestinal inflammatory affections, and took several doses of hemlock. Under this treatment the sickness and hæmatemesis with which it was at times attended, left her entirely, and a hæmaturia, to which she had become subject, ceased nearly at the same period. A short time after-

wards she had a pretty severe attack of erysipelas of the face, which was speedily subdued by the general abstraction of blood; but the sides of the puncture in the arm, though it had been made with a clean and sharp lancet, afterwards inflamed, and the irritation extended to the surrounding subcutaneous cellular substance. Leeches were applied, and the arm was enveloped in a poultice. Over all the parts so covered, a very plentiful crop of vesicles was soon observed to have arisen, which, bursting almost immediately after their formation, left the dermis beneath naked and exposed. This first eruption was before long succeeded by another, the bullæ of which varied in size from that of a pea to that of an almond, and only presented this peculiarity: that they either formed portions of an arc of a circle, or were too minute to be distinguished as possessing any determinate figure. These bullæ were almost always developed around the margins of the primary excoriation, which only spread in this way. The successive eruptions of bullæ had followed each other so quickly, that on the 6th of September, in spite of four bleedings of fourteen ounces each, in all of which the buffy coat was observed in as great perfection as it appears in articular rheumatism of the most violent kind, and two applications of leeches in the neighbourhood of the eruption, the excoriated surface resulting from the rupture of the bullæ, was from six to seven inches in length, by about three in breadth. Around the edges of the sore, sometimes separated from it by a narrow stripe of sound skin, sometimes touching it on one side, new bullæ of various shapes and about the size of hazelnuts, were still arising. The excoriated surface was slightly raised above the proper level of the integuments and mamillated; it secreted a considerable quantity of pus; here and there it was covered with patches of false membrane, and in other places with points of newly-formed cuticle. When the mamillated parts were pierced with a needle, or squeezed between the ends of the fingers, a small quantity of serum was expressed. The whole excoriated surface was excessively painful, and each dressing was followed by a violent shivering fit, which lasted two or three hours, and then gave way to a hot stage of some intensity. The pain came on in paroxysms, very commonly about midnight. The countenance of the patient was pale, the tongue slightly furred, the abdomen was free from all complaint but constipation. The mildest dressings were applied to the sore, the patient took the warm bath repeatedly, and the antiphlogistic treatment was enforced; nevertheless there was a fresh crop of bullæ almost every day, which was always preceded by violent pain in the arm, so that the patient, before the dressing was commenced, could predict the appearance or non-appearance of a new eruption, and even point out the places, where, in case of its having happened, the bullæ would principally be found.

At different times the sore put on a better appearance, and showed a disposition to heal, but on a sudden this favourable state of matters passed away, and our hopes were disappointed. No change of the dressings seemed to do any good, and nothing was gained by any form of lotion or fomentation.

After the 8th of October the arm was firmly rolled from the fingers to the shoulder, and the excoriation became completely skinned over, so that up to the 17th no new bullæ had appeared; but in the night, between the 17th and 18th, according to the patient's account, the pain returned with so much violence, that she was forced to undo the bandage, and next morning the parts first affected were found covered with an immense number of bullæ, of large size, and full of transparent serum. These vesications were all opened, and the roller re-applied. Several brown points being observed upon the skin when the dressings were removed on the 24th, a suspicion arose that they consisted of powder of cantharides, and on the 27th, a quantity of this article, easily recognizable by the changing bright green and brown colour of its particles, was discovered on the shoulder of the patient. The bedding being now carefully searched, two ounces of flour of mustard and a broad piece of cloth sprinkled over with cantharides in powder, were discovered. The woman, when questioned, acknowledged that she had applied these substances to excite new bullæ, undoubtedly with a view to prolong her stay in the hospital. A few days of uninterrupted watching, and the careful application of the roller, after this discovery, sufficed to heal up the excoriation completely, and to prevent the appearance of any more vesications.

<sup>1</sup> Histoire des phlegmasies chroniques, t. iii. p. 96, in-8. Paris, 1822.

314. Other causes, besides those now specified, may give rise to the development of artificial bullæ. M. Brachet informs us that he induced a pemphigoid eruption on the arm of a man affected with paralysis, by exposing it to the current, from a powerful galvanic battery. Wichmann,<sup>1</sup> and Messrs. Bourdois, Thillaye, and Guerin,<sup>2</sup> have seen erysipelatous and bullous eruptions, produced by the rhus toxicodendron and rhus radicans.

315. Lastly, M. G. Pelletan has published a case in the *Journ. de Chimie Médicale*,<sup>3</sup> in which a bullous eruption was produced on the fingers, by handling balls for poisoning rats, prepared with nuxvomica in powder, cheese and bitter almonds.

## VESICULÆ, OR VESICULAR INFLAMMATIONS.

Vocab. *Vesicle.*

316. This group is characterized by vesicles, or small serous and transparent elevations, differing from bullæ in nothing but their smaller size, and formed by a globule of serum with or without coagulable lymph, effused beneath the cuticle. These minute drops of serum may be either re-absorbed, or shed upon the surface of the skin after the rupture of the vesicles, which are succeeded at length by desquamation, superficial excoriation, or small thin and laminated crusts or scabs.

Five forms of vesicular inflammation of the skin are reckoned: Herpes, Eczema, Hydrargyria, Scabies, Miliaris sudatoria, and Sudamina; to these, however, must be added vesicular syphilis, and artificial vesicles.

317. The vesicular character of scabies has been disputed by Bateman, who ranks it among the pustular affections. The mistake he committed has been exposed by M. Bielt.<sup>(a)</sup> On the other hand, Bateman has classed vaccinia, aphthæ, rupia, and varicella, among the vesicles. But the vaccine pock is indisputably a *pustule*; aphthæ cannot be counted among the diseases of the skin; and rupia is a bullous affection. With regard to varicella, I grant that of the three or four varieties which the disease presents, severally designated under the names *chicken-pox*, *swine-pox*, and *modified small-pox*, one at least, the *chicken-pox*, is perfectly vesicular in its form; but it is also certain that the other varieties mentioned, and particularly the *modified small-pox*, are invariably pustular diseases. Varicella, therefore, by this double character, may be regarded as forming the link of transition from vesicular to pustular eruptions. Feeling myself free to attach it to one or other of these groups, I have preferred classing it among the *pustules*, with a view of approximating it to variola, of which it is a mere modification.

Vesicles are sometimes accidentally developed in the course of other diseases; but they are then few in number, and form true complications of the original malady.

318. The evolution of vesicles upon the skin is not preceded by any appreciable degree of redness in scabies, or in sudamina. On the other hand a great degree of redness precedes the eruption of herpes, eczema, hydrargyria, and sweating miliaria. It shows itself under the form of red *points* or *spots* of greater or less extent, on which the vesicles subsequently arise. The size of the vesicles in several varieties of herpes is rather considerable. In eczema, on the contrary, the vesicles are so minute that they are only distinctly visible under the magnifier. Occasionally it is even impossible to perceive that an elevated patch is vesicular without pricking it with a needle, when

(a) Justice is not done to Bateman in these observations of M. Rayer. The former defined scabies to be, "a contagious eruption of minute pimples, papular, vesicular, pustular, or intermixed according to circumstances, and terminating in scabs."

<sup>1</sup> Wichmann. *Ideen zur Diagnostik*, 1. B. p. 75.—*Nouv. mém. de l'Acad. de Berlin*, 177.

<sup>2</sup> *Gaz. médicale*, t. iii. p. 493.

<sup>3</sup> *Journ. de chimie médic.*, t. iv. p. 482.]

the escape of the serum proclaims its nature. The forms assumed by vesicles are not less various than their sizes. Those of miliaria are globular, those of herpes labialis, broad and flat, those of itch, acuminated, &c.

Vesicles may appear thinly scattered, or congregated into thickly set groups or clusters; their evolution is at one time simultaneous, at another successive, and the duration of each new crop may vary from a period of a few hours to one of several days in extent.

319. Vesicles may terminate, 1st, by the re-absorption of the fluid they contain, and a slight desquamation; 2d, by the transformation of this fluid into pus, and at a later period into thin laminated scabs, under which a new epidermis is produced; 3d, by the excoriation of the skin, which, becoming raw, first pours out a sero-purulent secretion, and then continues habitually subject to desquamation; 4th, and very rarely, by ulceration, as in zona and vesicular syphilis.

The vesicles in sweating miliaria never terminate but in the first of these modes; in herpes they often end in the second; and there is none of them in which eczema is not occasionally manifested.

The vesicular phlegmasiæ may be complicated with exanthematous, pustular, and other forms of inflammation. Two of them, itch and sweating miliaria, are contagious; the others are uninfected, and their etiology is often involved in great obscurity.

320. The vesicular are very different from the exanthematous inflammations. They are less unlike the bullous, from which, however, they are distinguished by the inferior size of the vesications that characterize them. The large bullæ of pemphigus cannot be confounded with the minute vesicles of eczema, of hydrargyria, and of sweating miliaria. Further, each of these diseases has its own peculiar and distinguishing characters.

The characters that distinguish vesicles from papulæ, tubercles, &c., have been already indicated (8), and by and by will be more particularly set forth.

The *incrustations*, the *furfuraceous scales*, and the *red marks* that follow some vesicular diseases, are distinguished with greater difficulty from alterations of an analogous kind, succeeding eruptions of a different nature. When speaking of each particular form of inflammation, I shall give the elements of the diagnosis in these difficult cases.

In the two-fold point of view of prognosis and treatment, vesicular inflammations present no common and generic characters for the guidance of the practitioner.

## HERPES.

Vocab. *Herpes, Dartre, Tetter.*

321. With Willan and Bateman I designate, under the name of *herpes*, a genus of cutaneous inflammations, not contagious in their nature, characterized by clusters of distinct vesicles inflamed at their bases, separated from each other by intervals of healthy skin, and drying off respectively and becoming covered with crusts in the course of one or two weeks. The different species of herpes, which resemble each other in the circular form generally assumed by their clusters of vesicles, differ in their seat (*herpes labialis*, *herpes præputialis*), in the arrangement of the several groups, which now appear scattered and far apart (*herpes phlyctenodes*), now disposed in the shape of a half girdle (*herpes zoster*), or in that of a ring (*herpes circinnatus*), and lastly, in the colour of the areola which surrounds them (*herpes iris*). (a)

(a) "Herpes" is a non-contagious affection of the skin, characterized by the eruption of clusters of globular vesicles upon inflamed patches of an irregular or rounded form, and of small extent. The eruption rarely presents any remarkable degree of severity; it is not usually accompanied by symptoms of constitutional disturbance; and it lasts for a brief period only; rarely longer than two or three weeks. Each vesicle runs a course of about ten days, and terminates either by absorption of its contents, by desiccation without rupture, or by rupture, and the formation of a thin, brownish scab, which speedily falls.

<sup>4</sup> *Der. eproué*, to creep.

Taken in the above acceptation, the word *herpes*, which has become classical, is not synonymous with the vague and indefinite name, *tetter* and *dartre*, by which the older English and French pathologists rendered it. It designates a class of affections, in the majority of instances, different from those which Lorry and some other pathological writers of the last and even of the present century, have grouped under the title *herpes*; it is now understood in a precise and rigorous sense which it does not possess in the nomenclature of the authors alluded to. (b)

#### HERPES ZOSTER OR ZONA.<sup>1</sup>

Vocab. *Zona, Herpes Zoster, Shingles, Ignis sacer, &c.*

322. *Herpes zoster, zona or shingles*,<sup>1</sup> is so denominated from the disease usually attacking one side of the body in the shape of a semi-circular belt or band formed by several clusters of agglomerated vesicles, which occasionally appear transformed into irregular bullæ by their conjunction, and the cure of which is commonly accomplished within two, three or four weeks.

323. *Symptoms.* The eruption of *herpes zoster* may be distinct, and characterized by scattered and not very numerous clusters of vesicles; more generally it is confluent, so that the vesicles of the various groups touch each other, or become mingled by their corresponding edges; in this case the epidermis may be detached over a considerable surface of the skin, as it is in extensive vesications from scalds or burns.

I have never met with *zona* as a chronic disease, and Willan makes no mention of this variety which is admitted by Lorry and Alibert, and of which Burserius quotes a case:—"Hanc speciem tamen diutinam non vidi, nisi semel in vetula quam stigmata pustularum sub omolata

"The varieties of *herpes* derive their designation either from the form and arrangement of the clusters, or from the locality of the affection. In reference to their general characters, these varieties admit of a natural division into two groups, a *phlyctenoid* group, and a *circinnate* group. The *phlyctenoid* group is characterized by the irregularity of form and distribution of the clusters of which it is composed; it is typified by the variety of *herpes phlyctenodes*, and embraces all the local forms. The *circinnate* group, on the other hand, is remarkable for the circular arrangement or form of its clusters; hence, the *herpes zoster* consists of irregular clusters disposed in a circular form around the trunk of the body; *herpes circinnatus* is characterized by the disposition of individual vesicles in the form of a circle; and *herpes iris* presents the same peculiarity in the form of concentric circles. In a tabular plan, the varieties may be thus arranged:—

1. <i>Phlyctenoid group.</i>	2. <i>Circinnate group.</i>
H. <i>phlyctenodes</i> ,	H. <i>zoster</i> ,
" <i>labialis</i> ,	" <i>circinnatus</i> ,
" <i>nasalis</i> ,	" <i>iris</i> ."
" <i>palpebralis</i> ,	
" <i>auricularis</i> ,	
" <i>præputialis</i> ,	
" <i>puddendalis</i> .	

(Wilson, *op. cit.* p. 157, Am. Edit.)

Dr. A. T. Thomson believes that there are only two distinct species of *herpes*, viz. *herpes phlyctenodes* and *herpes iris*. All the other forms, generally regarded as species, are, in the view of this experienced writer, mere varieties of *herpes phlyctenodes*, however they may differ in the figure of the clusters, or in the parts on which they appear.

(b) *Diagnosis.* *Herpes*, says Dr. A. T. Thomson, is distinguished from *pompholyx* by the vesicles appearing in groups or patches on an inflamed base; and from *erysipelas* by the vesicles not being preceded by redness and tumefaction; by their distinct yet clustered characters, and the state of the skin between the clusters. Neither *eczema* nor *impetigo* assumes the purely vesicular form, nor runs the same regular progress within a limited period; and both of them form their plates or semi-pellucid crusts, from under which a thin acrid fluid exhales, instead of the dry, hard scab which characterizes *herpes*.

<sup>1</sup> *Zona, cingulum, a girdle.*

*sinistra ad aliquot menses summo cruciatu atque ardore pertinaciter divexarunt.*"<sup>2</sup>

324. *Zona* may be developed on any region of the body; it is most frequently seen on the trunk, occasionally on the neck, face and scalp, on the scrotum and on the extremities. Like *erysipelas* it is occasionally preceded by a shivering fit, by headache, restlessness, insomnia, sickness of stomach, thirst and loss of appetite; the pulse is accelerated, the tongue is covered with a brownish or whitish fur, the patient is disinclined to exertion, &c. More frequently, however, the disease appears without any of these precursory symptoms. The evening before the eruption shows itself, the patient complains of prickling or smarting sensations, of burning heat or acute pain in the region which the *zona* is about to occupy.

In a previous edition of this work I remarked that of ten cases of *zona* which occurred, eight would be found on the right side of the body, without our being able to assign any cause for this anatomical disposition; and, since then, Messrs. Cazenave and Schedel have said, that nineteen in twenty of the cases of *zona* encountered, would be found occurring on the right side of the body. At present these statements do not seem to me based on fact: of fifty-three cases of *zona* which I have seen during the last few years, the eruption was developed on the right side in thirty-seven only. I may further add, that Reil tells us he has almost always seen *zona* invading the *left side*; and that out of twenty-five cases, Mehlis noticed sixteen on the *left*, and only nine on the *right side*. The discrepancy of these conclusions shows that accurate results will only be obtained when calculations have been made from data much more extensive than any that have yet been used.

1st. *Zona of the trunk* is the most common of all the varieties of this disease. The parietes of the abdomen are more frequently its seat than those of the thorax. The disease begins in some point of the mesial line, and proceeds outwardly and around the body till it approaches the plane of the vertebral column, forming in this way a sort of half girdle to the body. I have never seen *zona* form a complete belt; in such a case it would be almost impossible to distinguish the disease from *herpes phlyctenodes*. Pliny, Turner and Roussel have mentioned this disposition of *zona*; but they have neither given nor referred to any authentic instance of its occurrence. The case published by Mr. Montault, deserves to be quoted:<sup>3</sup> P \* \* \*, aged twenty-six years, complained of symptoms of gastric disturbance; on the seventh day he felt a violent pain in the right side, without cough or affection of his breathing; three days afterward there appeared on the right side, below and to the outside of the axilla, a number of erythematous patches, in the middle of which small whitish vesicles were before long evolved; from this point the eruption spread successively to the front of the chest, then to the back part of the body, and lastly to the left side.

*Zona of the trunk*, at its height, presents itself under the form of a semi-circular belt of variable breadth, formed by several rounded or oval groups of silvery gray or yellowish-coloured vesicles, occasionally mixed with irregular bullæ, surrounded by a red areola, and filled with a serous fluid either transparent or sanguinolent in its appearance. The eruption of these vesicles is preceded by irregular blotches of a rather vivid red colour, which sometimes show themselves at the two extremities of the belt, and are afterwards united by intermediate red patches, generally of an inferior size. These patches are soon crowned by numbers of small white silvery-looking and transparent vesicles of the form and size of seed pearls; in the course of three or four days they acquire the volume of a small lentil or large pea. The patches upon which the vesicles are evolved then become more florid, and the redness extends a few lines beyond the circumference of each particular group. At the end of five or six days the fluid contained in the vesicles assumes an opalescent appearance, becomes sero-purulent, and, when the inflammation runs high, is changed into true pus. Some of the vesicles burst spontaneously on the second, or from that to the fourth day, and pour out a little limpid and inodorous serum; the cuticle is detached, and the vascular rete of the corion being exposed, suppurates for a few days. Others, and indeed the greater number of the vesicles, dry up and become covered with small yel-

<sup>2</sup> Burserius. *Institut. med.*, vol. ii. p. 39.

<sup>3</sup> *Journ. hebdomadaire*, 2e série, t. iv. p. 259. *Zona* formant une ceinture autour du tronc.

lowish or brownish incrustations, usually lamellar in their texture, occasionally prominent, arranged in the form of a band, like the original eruption, and detached before long from the skin; others in fine shrivel up and disappear, the fluid they contain being reabsorbed.

The greater number of the vesicular groups of zona appear in succession, one after the other; whilst those that were first evolved are drying off and becoming purulent, new clusters arise in the intervals between them, and pursue the same course. When the disease affects the parietes of the thorax, the new groups occasionally spread across the shoulder so as to form a sort of T., by their junction with the others. A similar disposition of the vesicular groups is observed when the parietes of the abdomen are the seat of the disease, and the new crops of vesicles extend to the thigh of the corresponding side.

After the lapse of eight days at soonest, and of three weeks at latest, dating from the period of the attack, the whole of the incrustations of distinct zona are detached. The disease then leaves no traces of its existence, except *marks of a deep red colour*, which disappear by slow degrees, the peculiar oblique and belt-like disposition of which long reveals the nature of the eruption that has produced them.

The eruption does not terminate so speedily when the vesicles are confluent, and the skin that supports them is very much inflamed; in drying they are then covered by very adherent incrustations of a yellowish-brown hue, under which the skin occasionally becomes ulcerated and cicatrizes slowly.

Another and more disastrous consequence is occasionally observed: the part of the skin covered with vesicles on the posterior aspect of the trunk, is stricken with *gangrene* or a *softening of its texture*, whether from the effects of the inflammation, or in consequence of the continued pressure which this portion of the integument endures in the supine position of the body is uncertain. The eschars that then result have ragged and irregular edges, and do not always extend to the whole thickness of the skin, as I have many times ascertained by passing a probe over every part of the surface of the succeeding ulcer. The eschars are thrown off with greater or less celerity, according to their extent and thickness, and according to the age and vigour of the patient. If the skin be minutely examined after the fall of the sloughs, it appears as if a layer of the dermis had been removed with a shaving implement, leaving the part that remains white, and sown over with small red points; these seem owing to the penetration of the cellular prolongations and minute vessels that permeate the interstices of the tissue. When the eruption has been confluent, the skin that surrounds the excoriations remains red for a great while, and the cure is long looked for in vain. The cicatrices of these ulcerated spots are indelible; I have seen several which resembled the scars remaining after the cure of extensive burns.

The general symptoms that accompany the development of zona, the fever, thirst, headache, &c., commonly decline in severity, and occasionally cease entirely on the appearance of the eruption. Local pain, however, which is at times very intense in its character, and of the smarting kind, continues to the end of the disease, and occasions distressing insomnia. This pain is now and then complained of, even several weeks after all traces of inflammation have gone from the integuments affected. I have remarked it constituting the principal feature of a zona that aborted, or was imperfectly developed; this was in a patient who carried a single group of the vesicles of herpes zoster under the shoulder blade, and who complained at the same time of a very acute pain confined entirely to the left side, and extending like a belt from the spine to the sternum.

2d. Zona of the *neck* is more uncommon than zona of the trunk. I have seen this variety accompanied by very acute inflammation of the sub-mastoid lymphatic glands.

3d. When zona is developed on the *face*, the inflammation frequently extends to the mouth, one side only of which it likewise attacks. An old man, seventy years of age, was received on the 7th of January, 1827, into La Pitié, labouring under a chronic bronchitis; on the 13th of the same month, a vesicular eruption was thrown out on the left cheek, which, for three or four days previously, had been the seat of acute pain, shooting in the direction of the branches of

the portio dura. The skin of this side of the face presented a number of small red and slightly livid spots, which disappeared with pressure at first, but soon became changed into groups of vesicles similar to those of zona of the trunk of the body. Before long, the mucous membrane of the alveolar arch of the upper jaw, which was without teeth, and the inner surface of the left cheek were covered with vesicles, isolated or in clusters, and with several irregular bullæ of various dimensions, similar to those of the face. Vesicles of the same nature were also discovered on the left arch of the palate. On the last-mentioned part they were most numerous in the vicinity of the alveolar arch; they were all of irregular shapes, round, oval or elongated, and appeared to be surrounded by slight areolæ. This affection was preceded by prolonged shivering fits and constipation of the bowels. On the 14th, the fluid of the vesicles near the nose was partly changed into yellowish crusts; other vesicles that were just appearing were more prominent; of these, one small cluster was situated over the temple. The patient had complained, the evening before, of very violent pains in the left side of the face, and of a severe aching in the same side of the head. On the 26th, the vesicles of the temple, and of the external surface of the cheek, which were the first that appeared, were dried up; those of the interior of the mouth were yet distinguishable; the pain, still confined to the left side of the head and face, had recurred and continued through the whole of the night. On the 17th, the clusters of the face were succeeded by brown scabs, thin, where the vesicles were isolated, and distinct, thick, and analogous to those of impetigo, in those places where they had been confluent. Those of the inside of the mouth that had disappeared after an exfoliation of the epithelium, were replaced by small red spots.

4th. Zona attacks the *hairy scalp* still more rarely. A. B., forty-seven years of age, on the 27th of October, 1827, felt a severe smarting pain in the left eye and eyebrow, which soon spread to the forehead and cranium of the same side, without extending downwards to the face. Twelve hours after the commencement of the pain, vesicles, disposed in clusters, began to appear on the eyelids of the affected side, which were closed, and from between the edges of which a serous fluid kept distilling. Next day the left side of the forehead, and head generally, as far as the lambdoidal suture, was covered with small clusters of vesicles, similar to those of the eyelids, none of which passed the median line to trench upon the opposite side. On the 30th, these small clusters, scattered over the forehead and hairy scalp, presented the following appearances: the vesicles that had been formed most recently were not larger than the head of a pin, and contained a very transparent and limpid, yellow fluid; others were primarily of a larger size, or had become so by the fusion of several smaller ones; lastly, those that had been earliest evolved were completely dried up, and covered by a small black scab, set, as it were, within the substance of the skin around. All the remaining clusters dried up, as they do after their development on other parts of the body.

5th. Zona *perpendicular* or *parallel* to the axis of a *limb* is not of such rare occurrence as has been supposed; I have met with several cases of the kind; and others may be found recorded in periodical publications. When the disease attacks one of the lower limbs, the groups of vesicles are commonly scattered over the right or left lumbar region, the thigh, leg and foot.

I have, also, although rarely, seen zona developed on one side only of the skin of the *penis*, *scrotum*, *groin*, and verge of the *anus*.

7th. To conclude this enumeration, Marcus<sup>1</sup> speaks of a case of zona which appeared over the whole of one side of the body.

325. Zona seldom shows itself as a perfectly simple or uncomplicated disease. Psyraceous pustules occasionally occur in the midst of the vesicles that particularly distinguish it. The lymphatic glands of the axilla are often inflamed in zona of the thorax; this form of the disease I have seen complicated with pleurisy of the same side, a condition that was overlooked at first, the cough and local pain appearing to be sufficiently accounted for by the inflammation of the skin. I have, also, on many occasions, seen zona of the thoracic parietes, accompanied by bronchitis, of various degrees of intensity.

<sup>1</sup> Entwurf einer speciellen Therapie, B. ii. S. 213.

Among the internal affections that may be connected, or that may coincide with zona, there is, perhaps, none of more common occurrence than disorders of the stomach and bowels. Besides the precursory phenomena of zona being generally linked to symptoms of previous derangement in the alimentary organs, these often continue many days after the complete development of the eruption. I may add that other morbid conditions almost always accompany this vesicular inflammatory affection of the skin. One of these is a kind of neuralgia of the intercostal nerves which occurs in zona of the thoracic parietes; of the lumbar nerves, in that of the abdominal parietes; of the crural or the sciatic nerves, in that of the lower extremities, and so on. This neuralgic affection varies in intensity, and not only always precedes the development of the vesicular inflammation of the skin, but occasionally continues for several months after it is gone, and even requires particular medical treatment.

In this respect, as well as in the particular of their external form, there is a certain analogy between the vesicles of zona and those of the herpes labialis, occurring in intermittent fever. Another condition is a buffy state of the blood, which I have remarked in almost all the patients affected with zona, for whom I have had occasion to prescribe venesection.

326. *Alterations of structure.*—The anatomical structure of the vesicles and vesications of herpes zoster may be studied during life by opening them with the point of a pin or lancet. It will then be seen that besides serum the greater number of them contain a small piece of false membrane, which adheres very firmly to the vascular rete of the true skin below. The rete, of a vivid red colour, with small granulations formed by the papillæ scattered over its surface, occasionally presents minute points of a violet hue, especially under those vesicles that have been filled with bloody fluid. The quantity of serum effused is sometimes exceedingly small. In elderly persons I have observed the following disposition to obtain: the clusters well raised above the skin, distinct or confluent, and of the size of the largest vesicles seen in zona, were of a livid colour, flat on their surface, and so tough and firm that they did not give way under the pressure of the finger. By the eye it was impossible to judge whether they contained fluid or not; but a drop of limpid serum always escaped when the epidermis was pricked or raised by the point of a pin; and it was then evident that the violet tint and the hardness of the eruption were owing to a true elongation of the papillæ. In a case where the patient died, I had an opportunity of ascertaining that the vessels which penetrate the dermis were very much injected in the points corresponding with those on which the vesicles had been evolved.

The false membrane either does not exist, or is less apparent in those vesicles and vesications which have passed into suppuration. Those whose surface has become gangrenous, or that have been followed by excoriations, present different conditions, which I had an opportunity of examining at leisure, in the body of an elderly woman, affected with confluent zona of the upper part of the chest, who died towards the decline of the disease at the hôpital St. Antoine, of inflammation affecting the mucous membrane of the alimentary canal and air-passages. The excoriations were jagged, very irregular, and interspersed here and there with minute islets of skin, which appeared healthy, or simply red on its surface. The skin was destroyed to unequal depths on the excoriated points; in all it was softened, presenting in several a consistence no greater than currant jelly; the reticulated fibres of the dermis could not be distinctly made out; in sundry other places the skin, detached from the subjacent cellular membrane, was seen pierced with a few holes; in other places, again, it was completely destroyed through a considerable extent. The cellular substance only showed traces of inflammation here and there. The subcutaneous nerves, especially those which are supplied by the cervical plexus, examined with the greatest care, exhibited no appreciable alteration. The disease of the skin, though confluent, had not been accompanied by much pain.

327. *Causes.*—The causes of herpes zoster are little known. The disease is more frequent in summer and autumn, especially when the temperature is variable, than at other seasons. I saw a very great number of cases during the summer and autumn of 1827. Geoffroy, on the contrary, saw a great many patients labouring under the

disease in the month of March, 1778. Adults are more frequently attacked than children and elderly persons. I have known several persons suffer repeated returns of the disease in the space of seven or eight years, just as others are liable to renewed attacks of erysipelas, urticaria, &c. It has been observed as a hereditary disease;<sup>1</sup> it is neither contagious, nor has it been seen as an epidemic. Geoffroy,<sup>2</sup> indeed, says, that "many persons were attacked with zona in March, 1778," but he observes, at the same time, that the prevalent diseases were catarrhal affections of the head and chest. Very lately this cursory remark of Geoffroy, and several cases of the disease which had been accidentally collected within the same hospital, have been quoted as instances of the epidemic prevalence of zona. True epidemic diseases attack large masses of the population, not a few individuals.

328. *Diagnosis.*—The clusters of vesicles which characterize herpes phlyctenodes differ from those of zona in this, that they always appear on several regions of the body, such as the nape of the neck, the parotid regions, the ears, the sides of the chest, the axillæ, &c., and never assume the regular arrangement in a semi-cincture like zona. Several other particular characters further distinguish herpes zoster or zona, from herpes phlyctenodes, and the other varieties of this vesicular disease. The vesicles of almost all of these are smaller in size, and are never followed by the deep excoriations, nor the eschars occasionally observed in zona. With erysipelas, zona has only the functional derangement of the digestive organs, which so often accompanies both, in common; in the external and general characters of erysipelas, none of the local and particular symptoms of zona are to be discovered. Notwithstanding this fact, herpes zoster has actually been described by some authors as a species of erysipelas, probably because the surface affected by the latter is occasionally covered with a few phlyctenæ. But it seems impossible to confound the clustered vesicles of zona with the irregular and often very large bullæ observed in erysipelas. It is, indeed, true that the vesicles of zona, when they are confluent, occasionally change into irregular vesications; but then they are surrounded by areolæ that extend in proportion as the disease advances, and the vesicles and bullæ approach the period when they dry up and become converted into scabs or incrustations. Moreover, zona constantly appears in a form that is every way different from erysipelas. In the latter, the swelling of the skin, always much more remarkable than in zona, is accompanied by a tumid or puffy state of the subcutaneous cellular membrane. Erysipelas ends in a general desquamation of the surfaces it had affected, whilst the fall of the incrustations of zona is limited to the points that had been immediately occupied by its vesications and groups of vesicles. The form assumed by zona suffices to distinguish it from pemphigus. Zona only attacks a stripe or band of the skin; pemphigus is characterized by a single large bulla, or by numerous bullæ scattered over different regions of the body, which never extend in the form of a girdle. In zona, the accompanying redness spreads in a large areola around each cluster more and more widely as it advances toward suppuration, whilst in pemphigus, very slight and narrow areolæ are alone observed; occasionally, indeed, no areola whatever is visible; the redness of the skin in pemphigus, too, when it does occur, diminishes as the bullæ extend or dry up.

329. *Prognosis.*—Zona is never a serious disease among children or adults; in the aged it may be succeeded by sloughing and gangrenous ulceration, and these are accidents that always prove formidable. Langius<sup>3</sup> cites two cases in which this disease was fatal. Platner and Hoffmann have unquestionably alluded to cases of the same character when they speak of zona as a dangerous and malignant malady. Lorry, Burserius, Geoffroy and others have not noticed any cases of this description, which must, therefore, generally speaking, be held as exceptions; these authors do not see any thing alarming in zona. Of several hundred cases I have treated myself, I do not remember more than five or six that proved fatal, and the subjects of these were constantly aged persons. If Pliny, the naturalist, says that this disease becomes mortal when it forms a belt completely

<sup>1</sup> Lond. Med. Gazette, vol. ii. p. 632.

<sup>2</sup> Mem. de la Société roy. de Médecine, t. 2, 1778.

<sup>3</sup> Epist. Med., p. 110.

round the body, the opposite statements of Turner, and the observations of M. Montault, prove the assertion to be incorrect.

Herpes zoster sometimes forms the *crisis* of more serious affections. The interesting case related by W. Gulbrand, *de vertigne periodica per zonam solutâ* is well known. An instance of pleurisy consequent on the healing up of an ulcer, relieved by the eruption of herpes zoster, has been recorded.<sup>1</sup> In this case, however, the symptoms and characteristics of pleurisy are not rigorously set forth. On the other hand, the progress of zona may be modified by existing or intervening diseases. Two females, placed under the care of Dr. Recamier, were attacked with sciatic neuralgia: groups of vesicles, resembling those of herpes zoster, appeared here and there upon the thighs and legs of the affected side; but instead of increasing in size, of attaining maturity, and, in a word, running the usual course of zona, they became flaccid almost immediately after being thrown out, and soon dried up, so that after the fourth or fifth day no farther traces of the eruption were visible.<sup>2</sup>

330. *Treatment*.—When zona is preceded by severe pain, heat of skin, and acceleration of pulse, a bleeding from the arm, or the application of a number of leeches to the verge of the anus, or to the epigastrium, is often a useful measure; these symptoms, however, are commonly soon abated by rest, spare diet, and cooling drinks. The primary symptoms may either decline immediately, or continue with nearly the same intensity during several days, and compel us again to have recourse to the lancet, especially when the blood at first abstracted has been buffy. I have by this means treated successfully the insomnia and pain attending zona with fever, in a considerable number of cases. When the patients have refused to be bled, I have ordered the application of a line of leeches along the most painful parts, and an anodyne draught to be taken at night. The speedy relief that is so speedily obtained in this way, is always looked for several days before it arrives, when the treatment is limited to the purely expectant method. In general, blood-letting, which is prejudicial in the cases of elderly persons, and unnecessary in those of persons in the vigour of life, when the eruption is inconsiderable in extent, and not very violent in character, is very beneficial in cases of zona that are accompanied by violent pain and high fever, when the age and the constitution of patients warrant us in having recourse to the measure.

I have frequently seen the tartrate of antimony prescribed in the beginning of shingles, and I was myself for several years in the habit of employing this medicine, when the disease was accompanied by symptoms of gastric derangement; but I am now satisfied that the complaint went on, unmodified for the better, even to the time of the complete desiccation of the vesicles; the purely expectant method was even more fertile in results. (a)

Emollient topical applications hinder the vesicles from drying up, and seem rather to induce than to prevent excoriations. Opiate liniments have the same ill effects, but they allay pain, and induce sleep, when they are applied to the ruptured vesicles, or excoriated surfaces. They never cause the recession of the disease, which several writers have apprehended.

When the disease is confluent, and the cuticle is raised or removed from a great extent of surface, or, otherwise, when patients do not consent to keep their beds, it is proper, if the vesicles be not touched with any escharotic substance, to protect them from the friction of the clothes, by powdering them with starch, or covering them with tissue-paper, impregnated with oil and laudanum, or a piece of soft lint spread with cerate, retained in its place by a light bandage.

Patients, and especially such as are advanced in life, ought to be careful to lie habitually on the unaffected side, a precaution without which they will run the risk of inducing gangrene in one or several

of the clusters. Should any of these small eschars chance to be formed, they are to be covered with a piece of sticking-plaster until they are thrown off, when the ulcerated or perforated skin is to be dressed with camphorated ointment, and a soft compress of dry lint. If the sloughs are large and penetrate deeply, they are still to be dressed in the same way, with the greatest care and regularity. A slight application of the nitrate of silver, at intervals, often hastens the process of cicatrization. Internally wine, or wine and water, should be allowed; wine and the decoction of bark are the diet drinks of the aged.

Turner recommended the vesicles of shingles to be denuded of their cuticle; M. Serres proposes to cauterize them, with a view to shorten the period of the eruption, and to lessen its attendant pain. I have tried the plan; the first five cases were not favourable in their results; all the patients complained that the process was very painful, and it did not seem sensibly to shorten the disease. I have, however, varied the mode of procedure of late, and I find now, 1st, that if, after having opened the vesicles, or removed the cuticle by excision, their bottoms be very lightly touched with the nitrate of silver, in the same way as is often done in aphthæ, the duration of shingles is abridged, and that, on the contrary, it is prolonged, if the escharotic be too freely and carelessly applied; 2d, that the vesicles, when properly cauterized, are more rarely followed by excoriations, or by eschars, than those that are left to themselves, especially in elderly persons, and when they are situated upon the posterior parts of the body; 3d, that this system, which may be omitted in slight and distinct cases of shingles, ought to be put in force whenever there seems reason to apprehend excoriations or eschars in any of the groups on the body, face, &c.; 4th, that in touching slightly the red patches which precede the eruption of the vesicles, and especially those which appear subsequently to the first crop of clusters, their further development is almost always arrested, but that the acute pain which accompanies them is not modified or abated.

As to the *subcutaneous pains*, which in various degrees of severity occasionally continue several months after the disappearance of shingles from the parts it had invaded, they are commonly relieved by the exhibition internally of hyoscyamus, belladonna, and powdered stramonium seeds; (a) by the use of local vapour baths, or of a succession of blisters along the course of the affected nerves. An old woman who suffered much from a neuralgic affection of this kind, was speedily cured by taking a drachm of the subcarbonate of iron three times a day. I have, however, met with many of these neuralgic affections which neither yielded to any of the remedies mentioned, nor to many more besides that were tried. I cannot better compare these obstinate pains which supervene after shingles, than to certain cases of tic-douloureux whose resistance to therapeutical agents of every kind is often truly deplorable. (b)

(a) Or, still better, of the extract of stramonium. More than mere analogy will direct the use of colchicum in these cases; also decoction of dulcamara.

(b) The following observations by Mr. Plumbe (*op. cit.* p. 214) are worthy of notice in the present connection. "Like the prickly heat, the eruption of herpes can never be checked [repelled?] by any medicine or medicinal application; and those, therefore, which relieve the sufferings of the patient, ought not to be neglected. Solutions of ceruss. acet., or the liq. plumb. acet. dil., with the addition of alcohol, may be applied with advantage by means of wetted linen; they lessen the pains in question, *but never check the eruption in its course*. The vesicles ought not to be cut or rudely broken, such a proceeding generally rendering the separation of the scab considerably more tedious than it would otherwise be; but if care be taken to puncture each individual vesicle early, so as to allow of the free escape of the fluid, the pain is much diminished, and the irritation sooner subsides." Dr. Mackintosh says that, in herpes zoster, leeches on the inflamed part, if early applied, will arrest the further progress of the disease. Plumbe has found blisters near the inflamed spot exert a similar effect.

<sup>1</sup> Pleurisy, with an eruption of herpes apparently critical. (London Med. Gaz., v. 1, p. 707.)

<sup>2</sup> Revue Médic., t. xxv. p. 435.

*Historical Notices and particular Cases of the Disease.*

331. Celsus signalizes the principal characters of herpes zoster in his description of the first species of *ignis sacer*, "Exasperatumque per pustulas continuas, quarum nulla alterâ major est, sed plurimæ perexiguæ. In his semper ferè pus, et sæpè rubor cum calore est, serpitque id nonnunquam sanescentre eo quod primum vitiatum est, nonnunquam etiam exulcerato, ubi ruptis pustulis ulcus continuatur, humorque exit qui esse inter saniem et pus videri potest. Fit maximè in pectore aut lateribus, etc."<sup>1</sup> Scribonius Largus considers it as a species of herpes, and distinguishes it from the *ignis sacer* "Zona, quam Græci *επειτα* dicunt."<sup>2</sup> Pliny entitles the disease *zoster*.<sup>3</sup> Several other names have been given to it in modern times, such as *zona ignea*, *zona serpiginosa* (Schwarz), *herpes zoster* (Willan), *erysipelas zoster* (Sauvages), *erysipelas phlyctenodes* (Cullen), *dartre phlyctenoïde en zone* (Alibert), *cingulam*, *shingles*, &c.

Schenckius<sup>4</sup> relates a case of *zona of the loins and thigh* that was cured by a bleeding from the foot. Tulpus<sup>5</sup> has given a good description of *zona of the trunk*. Turner<sup>6</sup> has published observations on shingles of the neck, of the trunk, and of the limbs. In the first edition of this work I gave an account of the disease affecting *the face and mouth*. Bergius,<sup>7</sup> Jos. Frank,<sup>8</sup> and M. Cazenave,<sup>9</sup> have each published notices of the disease affecting *the head and hairy scalp*. Hoffmann tells us that he had seen the eruption of *zona* preceded by anxiety and *delirium*.<sup>10</sup> Messrs. Serres,<sup>11</sup> Bedor,<sup>12</sup> Ern. Geoffroy,<sup>13</sup> Velpeau,<sup>14</sup> &c., have written in favour of the cauterization of the vesicles of *zona*. Pinel<sup>15</sup> and M. Louis<sup>16</sup> have given us histories of cases in which the pain continued for several years after the disappearance of the eruption; M. Molinié<sup>17</sup> and M. Lesénécal,<sup>18</sup> have inserted in their inaugural dissertations, the histories of many cases of *zona of the trunk and extremities*. In the two following cases the disease appeared in quarters where it is very rarely seen.

CASE XXXVII. *Herpes zoster of the left side of the face, and of the inside of the mouth.* M. M. \* \* \*, twenty-seven years of age, and of regular habits, entered the Hôtel Dieu on the 29th of March, 1826. On Thursday the 23d, without known cause, this patient felt slight shooting pains in the left ear, which became more severe on the 24th, and extended to the neck. Whilst smoking, as usual, on the 25th, he felt severe prickling pains in the tongue, which one of his friends examined, and told him it was *white*. In the night, between Saturday and Sunday, a number of small blisters were developed on the left cheek close to the ear, which on Monday and Tuesday became more numerous and spread over the chin. On Wednesday the patient went out and got chilled; on returning home he continued to shiver for three hours. This cold fit was succeeded by a burning heat that lasted the whole night. The patient did nothing for himself until Sunday, when he had a little olive oil dropped into the ear that was painful, and washed his mouth repeatedly with vinegar and water. Wednesday, 29th of March, the day of the patient's admission into the hospital, the disease was in the following state:

The left cheek is swelled, hard and hot. From the ear to the chin, over a surface about three fingers' breadth in extent there is a band of bullæ and rounded vesicles, of different sizes. The vesicles are from half a line to a line in diameter, and are separately disseminated, or gathered together in clusters. The bullæ are much more voluminous than the vesicles, but much fewer in number; they are from four to

six lines in diameter. Many vesicles appear about their circumference. Several of the bullæ and vesicles are transparent, and contain a limpid fluid; others are of a dull white colour, and are filled with what appears to be purulent matter. Both bullæ and vesicles are mingled with many irregular yellowish and soft incrustations.

There is a copious secretion of pus from the meatus auditorius externus. Neither redness nor ulceration are apparent in this part; but the concha is covered with several small vesicles.

The left half of the tongue is swelled, thick, red, and covered with soft whitish plates of an irregular shape. Some of them are of the size of the vesicles, others nearly as large as the bullæ that exist on the skin. These plates appear to be about as thick as a sheet of paper. Several of them formed of the epithelium thickened, are almost detached. White patches or spots of a similar kind are observed on the inferior surface of the tongue, on the inner side of the left cheek and left half of the gums and lower lip; but none are to be seen on the palate, nor on the upper lip. Lastly, the affection appears to be limited in the most precise manner by the median line: the right half of the mouth and particularly the right half of the tongue, have their natural colour and appearance.

The saliva, which is abundantly secreted, is ropy; the breath is offensive, but has nothing of the mercurial odour. The patient neither complains of heat nor unpleasant taste in the mouth. The pain of the ear is much less to-day; he does not complain of headache, has no cough, little inclination for food, less thirst; the bowels have been locked up during the last three days; the abdomen is not tender, even on pressure; the urine is natural; the pulse strong and full, not febrile in its character. (*Venes. ad 3xii; veal broth for drink; lavement, gargle of barley water with honey and roses; spoon diet.*) March 30th.—The vesicles and bullæ which were plump last evening, are changed into yellow scabs. Five new vesicles, as large as pin's heads, have been formed during the night. Several of the white plates that adhered to the tongue are detached. The pulse is quicker than it was yesterday, but not so full. (*Veal broth, gargle, spoon diet.*) April 5th.—There is now no trace of the white specks in the mouth. The left margin of the tongue presents a longitudinal furrow, bounded above and below by a prominent red line. The upper surface of the left side of the tongue is still red and uneven. When the patient thrusts his tongue out of the mouth, the point deviates to the right side. The secretion of saliva is much less copious than it has hitherto been; the left cheek is less tense; it is now neither injected nor hot. The scabs that have followed the bullæ and vesicles of the chin bear a slight resemblance to those of *impetigo figurata*. Three scabs are observed, differing from all the others, near the concha of the ear; these are brown, dry, like a small portion of horn, and are a little under the level of the skin. To these a poultice was applied. April 28th.—All the scabs have been thrown off. The skin of the chin, in several places, is callous, indurated, and covered with tubercles like those that succeed *mentagra*. From this time the patient continued quite well, and soon left the house.

CASE XXXVIII. *Herpes zoster of the left side of the face, neck, meatus auditorius externus, and part of the hairy scalp.*—B. Lambert, seventeen years of age, presented himself among the out-patients of the hôpital St. Antoine, on the 24th of August; on the 19th, this patient had complained of heaviness of head, and heat in the regions that were now covered by an eruption of herpes zoster, which, in clusters of various sizes, extended upwards from above the clavicle on the left side to behind the ear, to the cheek, and parts covered by the beard, and downwards over the fore and outer parts of the chest.

The clusters are everywhere of a bright red colour, which disappears under the pressure of the finger, and re-appears immediately on its removal. On several of them, less advanced than the rest, small vesicles are seen situated upon and projecting in a slight degree from the surface of a red patch of skin underneath. On the right side, behind the ear, and upon the scalp of the same side, these vesicles are more apparent than those of the groups scattered amidst the beard and over the chin. The patient assures us that these last have appeared since yesterday. One cluster is conspicuous in front of the meatus auditorius at the root of the hair; another is seen within the meatus itself.

The parts covered by the eruption are not particularly painful; the state of the general health is good, and the patient complains of no want of appetite.

The patient was not restricted in any way; at the end of the second week a few livid spots of the same shape as the previous clusters of vesicles were all that told of the existence of this eruption.

## HERPES PHLYCTENODES.

Vocab. *Herpes miliaris*, *Herpes phlyctenodes*.

332. Herpes phlyctenodes is characterized by clusters of globular and transparent vesicles, as large as millet-seeds, or the smallest peas, which appear in variable numbers upon red patches, usually of a circular form, and disseminated over different regions of the body.

333. *Symptoms*.—This species of herpes, which is excellently described and represented by Bateman, is occasionally developed on the forehead, the cheeks, and the neck exclusively; more frequently it appears first on the extremities, whence it spreads to various other quarters. Willan and Bateman conceive that herpes phlyctenodes is always an acute disease. I have seen it assume a chronic form, one crop of vesicles being evolved after another.

A sensation of tingling, of itchiness or painful smarting and pungent heat in the parts where the eruption is about to appear, is followed by the formation of minute and almost imperceptible red points clustered together, so as speedily to compose an irregular coloured patch, the breadth of which varies between that of a half-crown piece and that of the palm of the hand. Some hours afterwards, or next day at farthest, a number of hard, shining and globular vesicles, varying in size from that of a millet-seed to that of a small pearl or pea, arise on the inflamed patches. These are filled with serum, which is usually colourless, or of a pale citrine tint, but occasionally presents a brownish hue in the aged. The vesicles themselves occur in *irregular clusters* of different magnitudes, but consisting in general of from a dozen to about fifty vesicles. To these primary clusters, which are often not more than one or two in number, several similar groups succeed. The integuments preserve their natural appearance between the different clusters, but seldom between the several vesicles composing the particular groups. The tingling and smarting sensations are increased by augmentations in the external temperature and by the warmth of the bed during the night. The size of the vesicles in general increases with rapidity; some of them even acquire rather considerable dimensions, and appear formed by the confluence of several into one. Twenty-four or thirty-six hours scarcely elapse after the appearance of the inflamed patches, before the fluid in the vesicles becomes turbid. The smaller assume a milky hue; the larger turn brown and are filled with sanguinolent serum. The whole decline, or are broken, from the sixth to the tenth day, during which interval new clusters continue to arise. The fluid of the very minute vesicles is occasionally reabsorbed, and many clusters seem to miscarry; the fluid they contained is rapidly turned into yellowish or blackish scabs, which are usually loosened from the tenth to the twelfth day. The parts of the skin that have been affected retain for some time a red or livid colour; and a painful sensation of prickling or smarting, very similar to that which follows shingles, occasionally continues for some time after the eruption has disappeared. Several weeks after the cure of the vesicles, small circular yellow stains still show the points they have occupied.

Between the irregular clusters of the herpes phlyctenodes a few single vesicles, and occasionally a few pustules, make their appearance. In some rare cases the clusters of herpes phlyctenodes have a regular circular form, and the areas of the patches are covered by distinct, not confluent vesicles. This variety, which in England is known under the name of the *nirles*, is always attended with violent pain, and a notable derangement of the general health.

The appearance of phlyctenoid herpes is occasionally connected with some slight disorder of the digestive organs, proclaimed by tardy digestion of the food, by thirst, heat and oppression of stomach, tumid state of the abdomen, &c. In some cases this internal affection even attracts our attention more than the outward malady. Seve-

ral other symptoms precursory to the eruption, are also frequently observed: one patient complained for two days of acute pains similar to those of rheumatism or sciatica, and anon the disease made its appearance upon the two lower extremities. It may also occur in individuals labouring under other diseases: in an individual affected with a pulmonary catarrh, I have seen herpes phlyctenodes evolved on the face, the front parts of the thorax, under the axillæ, on the extremities and on the scrotum; in this case the vesicles were preceded by red patches several inches in diameter, slightly raised above the level of the skin, and were so minute that they could scarcely be distinguished by the naked eye. Among the clusters on the scrotum there were several that might very readily have been mistaken for something else, without attention to the nature of the neighbouring groups. The cutaneous eruption in this case had no influence either salutary or noxious on the progress of the bronchial affection.

The duration of herpes phlyctenodes varies considerably; usually lasting three weeks, it is occasionally much more protracted; the spots that follow the vesicles often continue visible for several months.

334. *Causes*.—Like those of shingles, the causes of herpes phlyctenodes are exceedingly obscure. The disease occurs more frequently in persons of mature age than among children and the aged; it is often observed to follow night watching, moral affliction, and other acts that powerfully excite or modify the nervous system. (a)

335. *Diagnosis*.—Herpes phlyctenodes cannot be confounded with pemphigus: the former being characterized by an eruption of vesicles, the latter by one of bullæ. Several circumstances, however, may conduce to obscure the distinguishing features of these two diseases.

In the first place we see that M. Alibert formerly described pemphigus under the name of *herpes phlyctenodes* or *dartre phlycténoïde*; but this is not the first occasion on which two different diseases have been called by the same name: to avoid error it is in this instance enough to be informed of its existence. On the other hand, the practice of employing the words *bullæ* and *phlyctena* as synonymous terms, ought to have led Bateman to avoid the use of the appellative *phlyctenodes*, which is calculated to continue the confusion of names. The old denomination of *miliaris*—herpes miliaris, or any other that bore reference to the size or disposition of the vesicles would certainly have been preferable.

Herpes phlyctenodes approaches pemphigus in its characters when the bullæ are of small size, as they are often observed to be in the variety designated *pruriginosus*; the bullæ of pemphigus, however, are seldom seen in groups. Farther, the bullæ in pemphigus *pruriginosus* are small, round and mixed with papulæ, whilst in herpes phlyctenodes, when the vesicles are large, they are angular or irregular in shape. When herpes phlyctenodes is complicated with accidentally occurring bullæ, it may be confounded with pemphigus conjoined to an herpetic affection; these two conditions form a sort of transition reciprocally from the one disease to the other. The bullæ of acute pemphigus differ too widely from the vesiculæ of herpes phlyctenodes to make the diagnosis in this case either uncertain or difficult.

In eczema the vesicles are rarely seen in clusters; I have, however, met with a few instances of this arrangement. The vesicles of eczema are always smaller and less prominent than those of herpes.

336. *Prognosis and treatment*.—Herpes phlyctenodes, the dangers of which have been strangely exaggerated by some pathologists, seldom appears on a great many regions of the skin at once. When it occurs, as it almost always does, with the acute type, it gets well of itself in the course of one, two or three weeks, in individuals of sound constitution. Its period may be shortened by cauterizing the vesicles. I always find it yields readily to cold or tepid bathing, to cool emollient and soothing lotions, to diluents and the antiphlogistic regimen, without having recourse to blood-letting. Nevertheless, in herpes phlyctenodes, as in shingles, when the patients are strong and the eruption is abundant, and so painful as to cause sleepless nights, a bleeding from the arm never fails of giving great relief. The blood abstracted under these circumstances is often found to be buffy.

Any increase of temperature adds to the pain and uneasiness. Cold

(a) Plumbe points out the fact, which must have been noticed by other practitioners, of the frequent occurrence of this disease in children during the period of dentition.

lotions and cold poultices applied to those clusters that are very much inflamed, occasionally give ease; but as they prevent the scabbing over of the vesicles, they are in general rather injurious than beneficial.

When the disease appears in children, Underwood recommends the juice of the *Pastinaca sativa*, in doses of from one to five table-spoonfuls, mixed with a small quantity of milk.

In brief, when the disease is acute, but inconsiderable in extent, it may be left to itself, for it gets well spontaneously in no long space of time; this at least may always be done when children are affected, as the application of escharotics alarms them greatly; but when adults are attacked the vesicles should be slightly touched with lunar caustic, and, if need be, a small quantity of blood abstracted. When the disease assumes the chronic type, and the vesicles appear in successive crops, a case which very rarely happens, experience shows that the use of purgative medicines contributes essentially to its cure, as it does to that of those eruptions generally, the development of which appears occasionally to depend on a buffy state of the blood. The violent pains that so frequently follow shingles, occur more rarely after herpes phlyctenodes, which also leaves cicatrices of the parts it has invaded less commonly than the herpes zoster.

#### *Historical Notices and particular Cases of the Disease.*

337. Bateman believes that it was this variety of herpes that Galen meant to designate, when he spoke of the *εγερς κηρυχέας* (*herpes miliaris*). The passages quoted by Foesius,<sup>1</sup> and all those I have consulted with the assistance of the *novus Index in omnia quæ extant Galeni opera, fol.*, Basil. 1562, appear to me too vague to be capable of any rigorous and precise interpretation. I even perceive as many of the characters of eczema as of those proper to herpes, in this author's account of the Roman matron who laboured under a *herpes of the ankle*.<sup>2</sup> Aëtius<sup>3</sup> repeats Galen. And the same vagueness of description, and the same uncertainty pervade the whole of the notices of herpes miliaris we meet with until the time of Turner,<sup>4</sup> who specifies the characters of the disease with precision. Willan and Bateman<sup>5</sup> have described it still better than Turner, and have figured it fairly. Russell<sup>6</sup> speaks of it under the very objectionable title of *herpes excedens*. Jos. Frank's<sup>7</sup> account of the disease is not marked by exactness, and is even obscured by false contrasts with other affections. Underwood<sup>8</sup> has spoken of its occurrence among children, and Alibert has described this variety of herpes under the name of *olophlyctide miliare*.

CASE XXXIX. *Herpes phlyctenodes of the face, preceded by pleurisy and erysipelas.* Rogers, admitted into La Pitié, on the 14th of January, 1826, labouring under pleurisy, which was arrested by the general and local abstraction of blood. A few days afterwards an erysipelatous inflammation attacked the face, for which sixteen leeches the one day and eight the next, were applied behind the ears and to the temples with the effect of immediately cutting short the disease. On the 12th of February an eruption of herpes phlyctenodes appeared on the skin of the face which was then losing its cuticle. Several clusters of vesicles were situated over the malar bone and masseter muscle of the left cheek, and on the frontal, temporal and nasal regions of the right side. The greater number of these vesicles were about a line in diameter, others were somewhat larger. They were unsurrounded by any red border, contained a whitish and semi-transparent serum, and were only distinguished at first sight from the rest of the skin by their white and silvery aspect. In the intervals between them the skin retained the pallid hue it had assumed ever since recovering from the erysipelas. The vesicles were developed without heat or pain of the skin. The tongue appeared a little red, yet the digestive functions were regular and the sleep was natural. On the 18th the vesicles had dried up and were succeeded by small scabs, in general of a thin texture and brown colour, though some of them were thicker

and of a yellow hue. An inflammatory affection of the gastric and bronchial mucous membrane succeeded this slight disease of the skin, and the patient continued for some time longer in the hospital.

CASE XL. *Herpes phlyctenodes of the body, face and lower extremities, preceded by catarrhus vesicæ, and followed by bronchitis.* Pierre Fort, aged 71, of good constitution, but with a yellow and bilious look, consulted me on the 19th of March, 1826. Three weeks previously he had had symptoms of retention of urine, which on the 14th, in consequence of some freedom in diet, became complete; fever set in and continued for eighteen hours, at the end of which time, and after drinking copiously of linseed tea, &c., he began to pass his urine without the use of the catheter. Since then P. F. makes water six or seven times a day. He complains of no pain in the hypogastric region, and shows none of the symptoms of chronic inflammation of the bladder. The object of his visit was to seek advice for another disease, herpes phlyctenodes complicated with bronchitis, which had first appeared on the 17th of March, during the violent sweating fit that terminated the febrile paroxysm brought on by the retention of urine. During the night between the 16th and 17th, several clusters of vesicles were observed on the front and lateral parts of the chest; a few vesicles were also evolved on the lips, alæ nasi and ears, during the course of the 17th. Next day he complained of tinglings in the buttocks, on which he could not rest without pain: the eruption had in fact extended to these parts.

19th. Many distinct and unbroken vesicles were seen on different parts of the face; several clusters in different stages were remarked on the chest, some of them transparent, others turbid, and filled with sero-purulent fluid; on the buttocks there were two distinct clusters, of rather larger dimensions than they possessed in other situations. These vesicles were everywhere of a much larger size than those of eczema; their base was very slightly inflamed, but still surrounded by a narrow red border. Besides the disease of the skin, I detected an affection of the bronchi. The inclination for food was not great; the sleep was interrupted by fits of coughing (*pectoral tisan, linctus, vegetable diet*). 24th.—The great number of the vesicles were now dried up; such as were not so far advanced, had a small yellow point in their centre; and others had been destroyed by rubbing. 26th.—The vesicles that had escaped destruction were transformed into black scabs, of an oval shape, and of the size of small grains of rice. 28th.—Small red spots indicated the points from which the scabs had been detached. The bronchial affection continued for some time longer than the disease of the skin.

#### HERPES CIRCINNATUS.

*Vocab. Herpes Circinnatus, Ringworm.*

338. *Herpes circinnatus*, or *vesicular ringworm*, is characterized by an eruption of small, globular, and very closely crowded vesicles, arranged in the form of rings, or completely circular bands. The portions of skin included within these are usually healthy, and the edges, more particularly, or the circlets, are seen to be studded with vesicles, and of a red colour of greater or less intensity. The duration of this eruption extends necessarily to no longer a period than a week or two, but it may be greatly protracted beyond this interval when the eruption of the vesicular rings is successive. It appears on the neck, cheeks, arms, shoulders, and other places, under the form of red and inflamed oval or circular spots, from half an inch to two inches in diameter, the evolution and continuance of which are accompanied by a very troublesome sensation of itchiness and smarting. The redness is less vivid in the centre than towards the circumference of the smaller spots. It is entirely wanting in the areas of the larger patches, within which the skin preserves its natural appearance. Small globular vesicles very closely set, whose bases are slightly inflamed, and which contain a transparent fluid, are rapidly developed around the circumference of the patches, at the same time that their areas become temporarily of a deeper red colour. From the fourth to the sixth day of the eruption the redness declines; the vesicles of the circumference become turbid, and then either burst, or are covered by small brownish scabs of extreme tenuity, which in their turn are

<sup>7</sup> Præcox univ. medic. præcepta. Art. herpes miliaris.

<sup>8</sup> On the diseases of children. Eighth edit., in 8vo. p. 182.

detached between the tenth and fifteenth day; at the same time a slight desquamation takes place from the centres of the spots when the redness has spread to them. Occasionally the fluid of the vesicles is reabsorbed, in which case they sink down, and are followed by an almost imperceptible exfoliation of the epidermis. The circlets of small diameter, covered with extremely minute vesicles are those especially that terminate in the manner just indicated; those of a larger size, and crowned with vesicles of greater dimensions, scab and scale off like herpetic eruptions in general.

Herpes *circinnatus* is never accompanied by any general functional derangement,—always understood that it is not complicated with another disease. It may be protracted for several weeks, when the patches and vesicles that characterize it are evolved in succession on different parts of the body. I have seen some of these ring-like vesicular clusters of the skin, surmounted by the bullæ of pemphigus.

Several of the children in the same school, or in the same family, are occasionally attacked with herpes *circinnatus* at one time; this circumstance has led some writers to conclude that the disease was contagious; the simultaneousness of evolution, however, may depend on other causes, such, for instance, as the impression of cold.

English authors having treated of the herpes *circinnatus* under the name of *ring-worm*, a title by which a variety of favus or scall, (*porrigo scutulata*,) undoubtedly a contagious disease, has also been designated, this confusion in the nomenclature has probably tended to keep alive the opinion that herpes *circinnatus* could be communicated from one individual to another. Herpes *circinnatus* cannot be, and never is, propagated by inoculation.

Herpes *circinnatus* is observed more especially among children, young people, women, and those whose complexion is fair, and skin is delicate. The causes of *chronic herpes circinnatus*, marked by its successive eruptions, are as completely unknown as are those of herpes *phlyctenodes*, or of pemphigus, when these diseases assume the same peculiar character.

Herpes *circinnatus* being the only disease of the skin which shows itself in the guise of an erythematous patch surrounded by an areola, or ring of vesicles, is easily distinguished when these are not destroyed. Should the vesicles, however, be shrunk, and replaced by a slight exfoliation of the epidermis from an exactly circular ground, this state may be confounded with erythema *circinnatum* towards its decline, or with a patch of lepra vulgaris freed from scales. In the first case some remains of vesicles on one or another of the rings will clear up the diagnosis; in the second, mistake seems next to impossible, for the erythematous rings of lepra vulgaris on the way to recovery disappear with extreme slowness; and it is very seldom, indeed, that there are not at the same time other leprosy spots to be found stationary, or whose cure is less advanced. As to favus in patches or rings—*porrigo scutulata*, or *pustular ring-worm*—this is a contagious disease, of long and uncertain continuance, and covered with scabs, which present peculiar and distinguishing characters.

Bateman recommends washes of sulphate of zinc, or borax, or alum, to soothe the itching that attends the formation of the vesicles in herpes *circinnatus*. The application of a linen rag dipped in plain cold water, and frequently renewed, answers the same end completely. Alkaline baths and saline lotions have likewise been successfully employed in this complaint. I am in the habit of recurring to slight cauterization with the nitrate of silver, with very good effects. In a word, the mode of treating herpes *circinnatus* does not differ from that which has been recommended in herpes *phlyctenodes*.

#### Historical Notices and particular Cases of the Disease.

329. Celsus, after having evidently spoken of herpes *zoster* under the name of *ignis sacer*, adds, *Alterum autem est in summæ cutis exulceratione, sed sine altitudine, latum, sublividum, inæqualiter tamen, mediumque sanescit, extremis procedentibus, ac sæpe id quod jam sanum videbatur, iterum exulceratur*.<sup>1</sup> This passage, which, in Bateman's opinion, refers to herpes *circinnatus*, is not to be interpreted in any very precise sense; but it seems to me rather to bear upon a variety of palmar *psoriasis*, which Alibert has described as a *dartre squameuse centrifuge*, than to the variety of herpes we are now discussing.

Turner has indicated this variety of herpes in a perfectly clear and positive manner, under the titles of *serpigo* and *ring-worm*.<sup>2</sup> In the fourth volume of the *Journal Hebdomadaire*, p. 197, and in the *Lancette Française*, vol. v., p. 9, some observations may be found on herpes *circinnatus*. I have given an instance (Case XXVII), of its complication with pemphigus.

#### HERPES LABIALIS.

Vocab. *Exanthema Labiale, Hydræa Febrile, &c.*

340. A slight degree of local heat, followed, before long, by a feeling of burning and tension, precedes and accompanies the formation of the clusters of vesicles that characterize herpes *labialis*. These clusters commonly form a sort of irregular ring, the circumference of which extends unequally towards the chin, the cheeks and alæ of the nose. The fluid contained in the vesicles, transparent at first, becomes turbid in the space of twenty-four hours, and then presents a yellowish-white colour, which ultimately merges into a puriform aspect. From the fourth to the fifth day of the eruption the vesicles burst or dry up; the fluid they contain escapes, or is changed into brownish or blackish scabs, which are commonly loosened about the eighth, or from that to the twelfth day, at which epoch there usually remains no further traces of this trifling inflammation beyond a slight red mark on the skin. If the scabs be picked off before they are completely dry, and a new epidermis is formed underneath, others are produced, the desiccation and detachment in which are much longer in taking place. This eruption is always attended with some degree of swelling of the affected parts.

Herpes *labialis* may be produced directly, by the action of external causes upon the skin of the lips, such as the impression of cold, occasioned by passing from a high temperature into a cold and damp air, the contact of acrid or irritating substances, &c. The complaint often appears during the course or towards the decline of an inflammation of the mouth, of a coryza, an angina, a catarrh, or a pneumonia; more frequently still does it follow an attack of intermittent fever, a circumstance that has not been noticed sufficiently by those who have treated of this slight complaint. All, however, have observed, that it was often preceded or accompanied by aphthæ, or vesicles in the mouth. I have seen the variety of herpes we are describing thrown out in the cavity of the mouth, and on the arch of the palate, accompanied by difficulty of swallowing, pains in the epigastrium, eructations, nausea, &c. Its appearance is occasionally observed to coincide with the decline or cessation of an inflammatory affection of the viscera.

Herpes *labialis* cannot be confounded with any other affection of the lips. The disposal of the vesicles in isolated groups, the considerable size which several of them attain, and their desiccation under the form of crusts, are so many particulars that preclude the possibility of confounding this disease with eczema occurring on the same parts. It is sometimes more difficult to distinguish this herpetic affection from vesicles artificially excited on the surfaces it usually invades.

Herpes *labialis* is at times a symptom of favourable augury in fevers, and the herald of a speedy recovery: *In febricantibus assidue fiunt pustulæ circà labia et nasum juxta febris solutionem*.<sup>3</sup> As in many other translations and Latin works, the word *pustulæ* is here used instead of *vesiculæ*.

This affection of the skin, which of itself is totally free from danger, rarely requires any other treatment beyond that indicated in the diseases which cause its development. Where the vesicles are numerous and confluent, however, and the pain, heat and swelling are considerable, cold and soothing lotions procure the relief, which the trifling nature of the malady often prevents patients from seeking. To hasten the desiccation of the vesicles, they may also be slightly touched with the nitrate of silver; [but if they be pricked with a fine needle on their first appearance, and the fluid they contain be squeezed out, they will be arrested in their progress, and scarcely show any scab afterwards, the unseemly appearance of which will consequently be avoided.]

<sup>2</sup> De morbis cutaneis, p. 73, 8vo. Lond. 1736.

<sup>3</sup> Ætius. Tetrabib., sermo 1, p. 234.

<sup>1</sup> De re medica, lib. v. sect. 28.

*Historical Notices of the Disease.*

341. Hippocrates certainly knew, and alludes to this eruption.<sup>1</sup> Observed by all, it has been described of late both by Willan and Bateman;<sup>2</sup> others have noticed it under the names of *eruption of the lips*,<sup>3</sup> *exanthema labiale* (Jos. Frank), *olophlyctide labiale* (Alibert). I shall not give any particular case of this slight affection, which presents few points of interest; many pathologists, indeed, have only mentioned it as a symptom common to several acute diseases.

## HERPES PRÆPUTIALIS.

Vocab. *Aphthæ, Ulcusculu præputii.*

342. Herpes præputialis is characterized by one or more groups of small globular vesicles evolved on the outer or inner surface of the prepuce, occasionally on both surfaces at the same time, and which disappear usually within the space of a fortnight.

The disease begins in one or several patches, six or eight lines in diameter, accurately circumscribed, and of a pretty vivid red colour. These are attended with a slight feeling of itchiness, more particularly towards their centre, upon which, between the second and fourth day, arise a number of small globular vesicles, containing a serous and transparent fluid, and, from their extreme tenuity, appearing to have the same colour as the parts upon which they are developed. The heat and itching increase and become more troublesome; the size of the vesicles augments, and on the third or fourth day the fluid they contain grows turbid and acquires a puriform appearance. When the eruption takes place on the inner surface of the prepuce, the rupture of the vesicles frequently happens as early as the fourth day; the epithelium is then detached, leaving the inflamed vascular rete of the corion exposed. A superficial sore is thus established, which, from the red or whitish colour it presents, and the character of its edges, which are but little raised, has often been mistaken for a syphilitic ulcer.

The character of this herpetic eruption is less equivocal when the vesicles are developed on the outer surface of the foreskin. The fluid they contain is either reabsorbed, or dries up on the fifth or sixth day; in the latter case it is changed into small dry scabs, lamellar or conoidal in their structure, which, being thrown off about the eighth or tenth day, completes the cure, if the parts have not been irritated by rubbing. It does not often happen that the accompanying inflammation is of violence enough to cause an enlargement of the lymphatic glands of the groin. Mr. Evans, however, has seen several cases of such a complication; but the inflammation of the glands never ended in suppuration.

The continual excitement to which the organs of generation are exposed, and the contact of fluids secreted by the vagina and uterus affected with chronic inflammation, are, of all the causes assigned for the production of this disease, those whose influence appears to be most fully established. I have thus seen the complaint reproduced again and again in the same individual. In similar cases, Mr. Pearson believes it may be caused by the use of mercurial preparations. Others imagine that they have observed it occurring most frequently in subjects who have had one or two attacks of venereal disease. Mr. Copland thought it occasionally symptomatic of an irritable state, or of actual stricture of the urethra. Mr. Evans and Mr. Plumbe, on the other hand, affirm, that it is often connected with a deranged state of the digestive organs. All are agreed that herpes præputialis is not a contagious complaint. Mr. Evans, it is true, mentions the circumstance of a friend of his having inoculated himself in the arm with the fluid of a vesicle developed on the prepuce, with the effect of exciting in the spot a much larger vesicle than the one that had furnished the poison. This experiment, however, repeated several times, not having been attended with the same consequences, and being in other respects inconclusive, the production of the variety of

herpes under consideration, even from Mr. Evans's showing, must be held to be independent of any specific cause.

The vesicles of herpes præputialis cannot be confounded with the syphilitic pustules and tubercles which are occasionally formed on the prepuce: each of these forms of inflammation has its own peculiar and distinguishing features. The *venerola vulgaris* of Mr. Evans is, of all the diseases of the organs of generation, that which might most readily be confounded with herpes præputialis. The venerola, however, commencing by a single pustule, and herpes being first perceived as a cluster of small vesicles, the two complaints may always be discriminated. Farther, the thin, scaly incrustations of herpes præputialis can never be confounded with the thick scabs of *venerola vulgaris*. The diagnosis is, indeed, more difficult when these affections occur on the inner surface of the foreskin, and have passed into the excoriated state. The patients are generally unable to say whether the inflammation was at first vesicular or pustular. The prepuce, too, may be in such a state of accidental inflammation, when affected with herpes præputialis, as to make the diagnosis uncertain for several days. The superficial excoriations of the herpes, however, are very different from the ulcers of syphilis, remarkable for their depth, their hard and raised edges, and the small gray-coloured false membrane that covers their bottom. In fine, the small, thin, flattened incrustations of the herpetic affection cannot be taken for the scabs of syphilitic pustules.

Herpes præputialis is a disease of no severity, and gets well commonly in the space of a week or two. When evolved on the outer surface of the foreskin, it is seldom that we are consulted by patients, unless, indeed, the vesicles have been excoriated or inflamed by the rude contact of the clothes, or the improper use of some irritating local application. It is generally best to leave the eruption to itself, only protecting the part against friction, inasmuch as all that interferes with the desiccation of the vesicles delays its cure. Mr. Evans knew a case in which this was prevented for six weeks, in consequence of the pains that were taken, by a variety of applications, to hinder the little vesicles from becoming covered with scabs. When the vesicles are situated on the inner surface of the prepuce and have become excoriated, their cure may always be brought about by the introduction of a small quantity of lint between the glans and the foreskin, or by the use of simple cold water, or acetate of lead washes. Herpes præputialis may recur repeatedly, at intervals so close together as to present all the characters of a continued chronic affection; in this case we often find a chronic inflammation of the urethra existing at the same time. The duration of herpes præputialis may be shortened by cauterizing the vesicles superficially.

*Historical Notices and particular Cases.*

343. Herpes præputialis, vaguely signalized under the names of *aphtha* and *ulcuscula præputii*, which were also applied to aphthæ or solitary vesicles, has been in more recent times carefully described by Royston,<sup>4</sup> Mackechnie,<sup>5</sup> and Evans.<sup>6</sup> I shall give a single case; others have been published in different periodicals and works of the day.<sup>7</sup>

CASE XLI. *Herpes præputialis: slight inflammation of one of the glands of the right groin.* M. N \* \* \*, forty years of age, married, and never having had any venereal affection. His wife has, for years, been subject to leucorrhœa, which is always more copious than usual after the menstrual periods. On the 3d of August, 1820, M. N \* \* \* came to ask my advice for an inflammation of the prepuce that had continued three days, and presented the following characters: on the exterior of the prepuce there were three small clusters of from eight to a dozen of rounded and semi-transparent vesicles; several other minute vesicles, and slightly excoriated points, were also seen on different parts of the inner surface of the prepuce, each

of which might have been covered with the head of a pin. The inner surface of the prepuce was more inflamed than the outer. The subjacent cellular membrane was itself a little swollen, and the foreskin could not, without pain, be retracted towards the base of the glans. One of the lymphatic glands of the right groin was slightly swelled and painful. All the other organs of the body seemed healthy. No change was made in M. N \* \* \* 's mode of living. The affected part was wrapped in soft linen to prevent it from being rubbed. The vesicles burst two days after I first saw the case, and for the most part, became covered by small, thin, blackish incrustations. A slight degree of excoriation succeeded the vesicles on the inner surface of the prepuce. This excoriation was washed with decoction of althea, and on the 15th of August the affection of the prepuce and the swelling of the gland in the groin had both disappeared.

HERPES VULVARIS, HERPES AURICULARIS, HERPES PALPEBRALIS, &c.

344. Vesicles of a kind similar to those of herpes *præputialis*, are occasionally developed on the upper eyelid in certain cases of ophthalmia, on the concha of the ear, in external otitis, and on the labia majora in women labouring under leucorrhœa, during pregnancy, or after delivery: a young woman had been confined a month; the labour and all besides had been prosperous; the lochia had disappeared on the fifteenth day, but a slight mucous discharge had still remained. This young woman took a very long walk, and the same day began to complain of uneasiness in the upper parts of the thighs, and of darting pains in the vagina, which wholly prevented her from sleeping. About the parts where the labia majora are continuous with the skin of the thighs, I observed two groups of vesicles, the greater number of which were globular like small peas, transparent, and so closely connected as to form little irregular bullæ. A plentiful secretion of mucus was pouring from the vagina, which was affected with shooting pains, over the labia and parts affected. A few hip baths, and the use of emollient and saturnine washes, soon put an end to these symptoms.

I also, on one occasion, had a young tradesman under my care, on the back of whose hands a great number of vesicles, similar to those of herpes labialis, had appeared. When I first saw him several of these vesicles had dried up, but others contained a sero-purulent fluid. An eruption of a like kind was repeatedly produced on the hands of a lad whose occupation was grinding colours, and who was in the habit of washing in water made very acid, after rubbing his hands over with soft soap. I have seen the same sort of eruption on the palms of the hands, and on the cushions of the fingers without any assignable cause. In these cases the fluid of the vesicles being covered with a very thick cuticle was in part reabsorbed.

#### HERPES IRIS.

345. Herpes *iris* is distinguished by small groups of vesicles surrounded by four concentric erythematous rings of different shades of colour. Patients affected with this eruption often compare it to small party-coloured cockades.

Herpes *iris* occurs most frequently on the backs of the hands, on the instep, olecranon, ankles, and similar parts. It commences with small circular red spots, composed of concentric rings of various shades, and which spread by degrees from two to perhaps eight lines in diameter. In the centre of each of these spots, from the second to the third day, there appears a flattened vesicle of a yellowish white colour, surrounded itself by several others of a smaller size, arranged in a ring. The central vesicle is surrounded by a first circle of a dull brown colour; this by a second, more external, and nearly of the colour of the central vesicle; this second is in its turn surrounded by a third circle of a deeper red; the third circle by a fourth, the areola around which is formed on the seventh, the eighth, or the ninth day, and presents a rosy hue which melts insensibly into the natural complexion of the skin. Of all these rings the third is usually the narrowest; they may all become covered with vesicles;

the first is most generally found so circumstanced. From the tenth to the twelfth day the fluid of the vesicles is reabsorbed, or it escapes and dries off under the form of superficial scabs, which are detached before the end of the second week.

Herpes *iris* has been observed to occur most frequently among children and females, either by itself or along with some of the other varieties of herpes. It is, however, very different from every one of these, and is the only form of cutaneous disease that is surrounded by several concentric rings. When the central vesicle has been destroyed, and the rings are not well marked, the disease is apt to be mistaken for roseola *annularis*; this, however, differs from the herpetic affection by the greater breadth of its discs, which occasionally extend beyond the space that would be covered by a crown-piece, and by the absence of vesicles or any remains of vesicles.

Herpes *iris* gets well spontaneously in the course of a week or a fortnight. Its period may be shortened by touching the vesicles slightly with the nitrate of silver. When blood-letting has become necessary on account of some co-existing affection, this evacuation has been found to shorten the continuance of the eruption. (a)

#### Historical Notices and particular Cases.

346. Herpes *iris* was established as a distinct species by Dr. Bateman, who has given an accurate description, and published a good figure of the disease. Dr. Marshall Hall<sup>1</sup> has given a lengthened history of its progress; and M. Ledebor<sup>2</sup> has related the circumstances attending a hereditary cutaneous disease which he thought analogous to the herpes *iris*. Alibert classes this eruption with his group of *ophlyctides*.

CASE XLII. Herpes *iris* affecting the regions of the olecranon and patella.—Michel, twenty-seven years of age, was admitted a patient to the fourth Dispensary on the 9th of March, 1826, and placed under my care and that of my colleague, M. Bayle. On the 5th and 6th of March, Michel had felt pains of the hips, elbows, hands and knees. On the following days these different parts became covered in succession with a vesicular eruption; but the patient continued at work as usual. The patient appears stout, of a sanguine and bilious temperament, and tells us he had an attack of the same kind last October, till which time he never suffered from any disease of the skin. On the 9th, vesicles, which had been thrown out on the lips six or seven days previously, were covered with thin brownish incrustations, and presented the characters that belong to those of herpes *labialis*. A single vesicle, situated on the upper lip, still contained fluid. The eruption over the olecrana and knee-pans, consisted of the herpes *iris*, and had only appeared within the last four days. The vesicles, which are about twenty in number on the right arm, less numerous on the left, are of the following description: in the centre of an inflamed surface, from four to six lines in diameter, a small vesicle, of a yellowish white colour, containing a little serum, and beginning to dry up, is perceived. The central point now described, is surrounded by a first ring of a reddish-brown hue, this by a second, nearly of the same pale yellow colour as the middle vesicle; a third ring, which is the narrowest, succeeds, and is of a deep red; and four days later, a fourth and more eccentric ring surrounded the whole, the rose red colour of which was insensibly lost in the natural colour of the neighbouring skin.

The vesicles about the knees were precisely similar in their characters. I ought to add, however, that upon the back of the right hand, and in the vicinity of the vesicles developed on the elbows and knees, there existed a small number of globular vesicles similar to those of herpes *phlyctenodes*, and containing a little limpid and transparent serum. These vesicles were all affected with a severe tingling, smarting pain. (*Venes. ad 3vi; bath; barley-water for drink.*) The desiccation of the vesicles was completed on the succeeding days,

(a) With Dr. Thomson, we are disposed to think well of moderate and gentle aperients in this species of herpes; to be followed by Fowler's solution and vegetable decoctions. A small piece of soap plaster is a useful topical application.

<sup>1</sup> Case of a particular eruptive disease. (Edinburgh Med. and Surg. Journ., 1820.)

<sup>2</sup> Bulletin des Sciences médicales de Férussac, t. xviii. p. 70.

and on the 15th of the month a few circular red stains upon the parts that had been affected were all that remained of this slight disease.

CASE XLIII. *Inflammation of the mouth; herpes iris.*—Fr. Germain, aged nineteen, of a lymphatic temperament, came into the hôpital de la Pitié on the 15th of April, 1826, on account of an inflammatory affection of the mouth, and a disease of the skin. In the month of April, last year, the patient had had an attack in the skin similar to the one he now labours under.

April 16th. On the legs and arms a number of spots are observed, the diameters of which vary from two to eight lines; one of them, nearly the size of a six-penny piece, is situated on the lower and outer part of the left arm; another at the bend of the arm; six more, two of which are as large as lentils, occur on the forearm, and a greater number are scattered over the left lower extremity. Two of those on the upper and outer part of the thigh are very close together; on the opposite lower limb several spots of the same kind occur, and two are visible on the buttocks. The greater number of these spots are formed by several concentric rings of a red or pink colour, each by its difference of shade rendered distinct from the others. The centres of all are occupied by a small, thin, brown scab, proceeding undoubtedly from the desiccation of a vesicle, from which, indeed, the patient says he evacuated the fluid by scratching the spots, which he knows made their appearance very lately, though he cannot tell precisely when. The spots are circular; the dimensions of the concentric-coloured rings vary, but are in proportion to that of the spots. Round the yellow central point there exists a first circlet of a deep red colour; this is inclosed within a second, more eccentric ring of a pink hue; these two rings are further surrounded by a third, of a deep and dusky red like the first; lastly, a fourth ring of a rose tint, which is gradually lost in the skin about it, encircles the whole. In the course of the next and succeeding days the second ring became covered with vesicles, and of a white colour, but the patient soon tore it with his nails, when a few drops of serum escaped. The whole of the spots were excessively itchy. By the 20th the little scabs in the centres of the spots had fallen off and exposed the pink surface of the corion, covered with a new epidermis.

The affection of the mouth had begun nearly twelve days before the patient sought admission into the hospital, by the development of aphthæ and an increased secretion of saliva. Two days afterwards, the swelling of the lips was followed by that of the tongue, and anon by inflammation of the throat. Deglutition became difficult and painful. The lips were covered with brownish or yellow incrustations. April 16th, the commissures of the lips are bleeding and inflamed; their mucous membrane, as also that of the gums, cheeks and palate, are covered with aphthæ or white prominent spots accurately defined on the inflamed mucous surface. The tongue is moist, and its upper surface is covered with a thick and whitish mucus. The mouth feels clammy, tastes bitter, and is so violently inflamed that the patient can scarcely unlock his jaws. The epigastrium is painful; there is considerable thirst; the bowels are constipated; there is no fever. (*Low diet, soothing gargle, barley-water for drink.*) 17th.—Greater swelling of the lips than yesterday; white confluent patches on the inner surface of the cheeks. (*Prescriptions as before.*) 18th.—The inflammation of the mouth has abated, and the secretion of saliva is less profuse than it was; bowels still unmoved. (*A glyster; a bath; broth and milk for food.*) 19th.—Desquamation over the upper surface of the tongue, which appears of a bright red colour, as in convalescence from scarlet fever. 20th.—The patient could open his mouth without pain; the inflammation declined gradually, and the patient was quite well by the 30th.

#### ECZEMA.

Vocab. *Eczema, Dartre, Gale, Tinea.*

347. Eczema is a non-contagious inflammation, often confined to a single district of the skin, characterized in its commencement by an eruption of very minute and not prominent vesicles, which are commonly very closely set or crowded together, and terminate either by the reabsorption of the fluid they contain, or by the formation of

superficial moist excoriations; to which succeed furfuræ and squamæ, or renewed eruptions of vesicles of the same nature as those that had preceded.

Although commonly limited to a single part of the body, eczema may become general, and appear simultaneously or successively in different districts. It seems in general to attack those regions in which the follicles are numerous and particularly apparent, such as the hairy scalp, the ears, more rarely the face, the trunk, the roots of the nails, the backs of the hands, and the superior extremities generally. It occasionally extends to the mucous membranes. In men it is often seen on the inner parts of the thighs, on the scrotum and verge of the anus; in women, it is occasionally developed on the mucous membrane of the nipple, vulva, and rectum; in children it particularly affects the face and hairy scalp, and occasionally extends to the inside of the mouth, to the nasal fossæ and external ear.

Eczema is *acute* or *chronic* in its type. In every case the disease is distinguished by the occurrence of one or several successive crops of eruption on the same region, or on different parts of the body. The vesicles themselves are agglomerated in broad patches, or arranged in irregular clusters; they very rarely take the form of bands in their disposition. When eczema is general, the whole of these varieties are occasionally witnessed in the same individual, in different degrees and in various stages of their progress. Under other circumstances one of them only is displayed with all its distinguishing characteristics.

348. *Symptoms.*—In acute eczema the eruption of the small vesicles that characterize the disease is announced by a sensation of smarting and sometimes by actual pruritus. They appear with or without redness, heat or tension of the skin, and present three varieties which are well described by Willan: 1st. *Eczema simplex*. 2d. *Eczema rubrum*. 3d. *Eczema impetiginodes*.

1st. *Eczema simplex*. In this generally very mild variety, the skin, covered with vesicles, almost always preserves its natural colour between the clusters. There is neither heat nor tumefaction; the vesicles, extremely minute, contain a globule of limpid serum, and usually correspond with the minute projections whence the hairs issue, and which may be very distinctly seen by examining the insides of the arms and thighs with attention. When the serum of the vesicles is reabsorbed, the cuticle that concurred in their formation shrivels, and is detached in the shape of a very minute plate or scale. More frequently still, the vesicles, after having existed for several days, burst or are ruptured by scratching, when the drop of serum escapes and gives place to a yellowish-coloured speck which, being before long thrown off, leaves a little pink spot, now dry, now moist and surrounded by a whitish circle, upon the skin. When the spot is moist, a very minute pore is perceived, whence a small quantity of serous fluid distils, which drying up forms a scab the size of a pin's head. Occasionally also, layers of the cuticle, altered in their nature, and thickened from the adhesion of the dried fluid of the vesicles, are detached from the skin. And it is at this stage that frequently, and without known cause, a new eruption of vesicles takes place, which follows in every particular the course of the first, when the eczema becomes chronic.

A variety of *eczema simplex* has been described by one of my pupils, Dr. Levain, which is not noticed by Willan, nor by any of the other pathological writers who, since his time, have given particular attention to the diseases of the skin. This variety is distinguished by clustered patches of vesicles, the dimensions of which vary from those of a sovereign to those of a two sovereign piece. The vessels of these clusters are numerous, very small, and in all respects similar to those of the other varieties of eczema, consequently they are much more minute than those that characterize herpes *phlyctenodes*. The clusters are scattered over the skin, which only appears red in the places affected. On the red patches covered with vesicles, the cuticle may sometimes be raised and removed in a single piece. Its inner surface looks moist, and covered with small whitish or deep yellow points produced by the fluid of the vesicles. The corion beneath is red, but not ulcerated; the clusters of vesicles here bear a resemblance to those of the herpes *præputialis*; and the variety of eczema we are describing, seems the link of connection between these two genera of vesicular eruptions.

*Eczema simplex* often extends to the whole surface of the body, especially in children, young persons, and subjects of an irritable constitution. The disease in general soon gets well, and relapses are not frequent. The diseases with which it may most readily be confounded are *certain vesicular eruptions, artificially produced* by the action of the sun's rays, and *lichen simplex*. To avoid mistakes in regard to the latter, it is enough to remember that the vesicles of the eczema contain serum, whilst the elevations of lichen are solid and yield a drop of blood when they are punctured.

2d. The inflammation of the skin is occasionally more intense than in the variety just described, and the disease is then entitled *eczema rubrum*. The part which is about to be affected with this eruption, swells, becomes hot, red and shining as in erythema and erysipelas. It is soon covered with small confluent vesicles, transparent at first, but speedily becoming milky, which burst anon, and pour out a little red-coloured serum. At a later period the cuticle, saturated with this fluid inspissated, becomes softened in some points and detached in others, when it dries into yellowish laminæ of little thickness, which are soon replaced by slight incrustations proceeding from the drying of the fluid poured out by the diseased surfaces. Lastly, the skin here and there presents small pink points around which the cuticle forms a true border with a jagged edge, indicative of the dimensions of the vesicles.

When *eczema rubrum* is very intense, the heat, redness and tension continue or even increase during several days; the vesicles are evolved, and burst with great rapidity; the fluid they pour out irritates still more the parts already very painful, and by its contact gives rise to excoriations of varying extent. The skin, stripped of its cuticle, and inflamed, appears beset with a multitude of pores each of which might be covered with the head of a small pin, from whence a red-coloured fluid exudes, sometimes in such profusion as to soak the clothes of the patient.<sup>1</sup> At other times the small vesicles unite, become blended together and form irregular bullæ analogous to those observed in certain cases of erysipelas. The epidermis, detached over a considerable space, bursts at length, a torrent of serum escapes, and the sub-epidermic layer now exposed and greatly swelled, besides the pores that have been already mentioned, presents false membranes of a whitish colour and soft consistency, which adhere slightly to the structures beneath. The serous exudation soon becomes less in quantity and ceases entirely; the cuticle, moist at first and slightly adherent, becomes of a yellowish or greenish colour, by being soaked in the fluids exuded; it then dries, falls, and is replaced by other laminated incrustations of a firmer and more permanent description. The skin loses by insensible degrees its tension and increased heat; the redness also declines, and the parts slowly recover their natural condition, the return to this being announced by the formation of a new and healthy cuticle. It frequently happens, however, that fresh eruptions break out, and the *eczema rubrum* becomes chronic.

3d. *Eczema* and *impetigo* have between them many strong points of resemblance, as well in reference to the parts of the body most commonly affected, as perhaps in regard to the constituent element of the skin, the follicles, in which they are both evolved; it is not, therefore, uncommon to meet in the same individual with *impetigo* affecting one quarter, and *eczema* developed in another. It often happens also that we find a mixture of the vesicles of *eczema* and of the pustules of *impetigo* covering surfaces of the integuments of greater or less extent, and still more frequently do we find the vesicles of *eczema* becoming purulent and giving occasion to an anomalous variety of the disease which has been described by Willan under the title of *eczema impetiginodes*. When this variety makes its attack in an acute form, the tension, heat and redness are considerable; it is not now mere tingling and itching that are complained of, but shooting and violent smarting pain. The vesicles now pass rapidly into the purulent state; the cuticle, raised in large flaps, is impregnated with the fluid effused, and acquires the appearance of greenish-coloured laminated scabs, which being before long detached, a surface is exposed of as bright a red as carmine. When the eruption is considerable, the ichorous fluid secreted is so profuse that dressings of every kind, and even the bed-clothes and bedding become drenched

<sup>1</sup> The disease in this form is described by French authors under the title of *dartre humide*.

with it; the smell of this matter too is as offensive as possible; it is faint and sickly, and something like that which a large burned surface, in a state of suppuration, diffuses. Around these *impetiginous* *eczemas* we commonly observe a tumid red circle, the surface of which is studded with small vesicles, transparent, milky or dry, according to their ages, and in all respects analogous to those that characterize *eczema rubrum*. The vesicles and incrustations are occasionally renewed successively and the disease becomes chronic.

*Eczema impetiginodes* may last several weeks, be transferred from one place to another, or lastly attack almost the whole surface of the integuments; most commonly, however, it implicates but a single region. When it shows no tendency to pass into the chronic state, all the symptoms decline, the inflammation lessens, the laminated incrustations fall off, the cuticle is reproduced, and the skin, of a violet colour, is unaffected afterwards, save by a slight exfoliation.

The three acute forms of *eczema* that have now been described, present shades of extreme variety. Most usually the morbid symptoms do not extend beyond the parts affected, or the structures in the immediate neighbourhood of these. Nevertheless when the eruption is very extensive, it is accompanied by disordered actions of a general nature; the pulse becomes frequent; there are thirst, anorexia, and the sleep is disturbed. The pain is increased by the heat of the bed; motion at times is impossible or attended with extreme suffering. The most common complications are inflammations of the lymphatic glands in the vicinity of the affected parts, and in some cases, especially in children, inflammatory disorders of the stomach or intestines.

4th. *Chronic eczema*. The three varieties of inflammation of the skin which constitute *acute eczema* may occur with the *chronic* character; this is even, it must be noted, the tendency of the varieties entitled *rubrum* and *impetiginodes*. After the bursting of the vesicles the inflammation often increases in severity, extends to the deeper structures of the skin, and even to the subcutaneous cellular tissue. Irritated by repeated eruptions of vesicles, and by the contact of an acrid ichor, the skin becomes excoriated, and presents chaps and fissures which every movement tends to make deeper and more extensive, especially if the disease occurs between the fingers, on the nipples, verge of the anus, or in the popliteal regions. In the greater number of cases the affected districts of skin present at first the appearance of a blister in a state of suppuration, and pour out a purulent serous fluid, of a disagreeable smell, which quickly penetrates any dressing that may be applied. These humid *eczemas* occasion intense pruritus, accompanied by severe smarting pains; the skin, highly inflamed, is stained with blood, looks of a violet colour, and seems beset with an infinity of minute pores, from which a sort of serous dew distils. Tormented by pruritus of the most violent description, patients thus affected talk of nothing but *heat of blood, inward fires*, &c. They cannot forget themselves in sleep; their sufferings, lulled for an instant, often return suddenly and without appreciable cause; nothing can then prevent or moderate the energy with which they begin to scratch themselves; a bloody serum flows from the torn surface of the skin; but, nothing assuaged, the pruritus continues as unbearable as before, particularly when the perineum, orifice of the vagina, or verge of the anus is the part affected; when left to itself, this cruel state often continues for months and even for years.

When the inflammation declines in severity, *chronic eczema* assumes another character. After the lapse of a longer or shorter interval, the vesicular, or vesiculo-pustular eruptions become rarer, and even end by not appearing at all; the scabs, at first moist and thick, and reproduced as soon as detached, grow thinner and thinner, drier, and more adherent to the skin, which at length appears covered by small, yellowish-coloured scabs,—the *dartre squameuse* ou *furfuracée* of some authors—among which, several bloody incrustations, the consequence of the excoriations caused by the nails of the patient, may be detected. The serous exudation is replaced by a simple epidermic exfoliation, to a greater or smaller amount. The more severe these *eczemas* have been, and the longer they have continued in this state, the longer is their complete disappearance expected, even after amendment has begun, and longer still are certain sequelæ, by which the previous existence of the disease may be certainly recognized, of being completely obliterated. Should a fresh eruption of vesicles chance to

appear on surfaces which either have been or are still affected with eczema, the new eruption bursts more quickly than that which is evolved on regions that have never before been attacked; these fresh crops scarcely continue entire above five or six hours in the former of these cases, a circumstance which is undoubtedly owing to the tenuity of the newly-formed epidermis. Lastly, it happens occasionally that slight vesicular eruptions are thrown out under the epidermis, thickened and altered by prolonged disease.

349. Having now described in a general way the *acute* and *chronic* states of eczema and the chief varieties presented by the affection, I shall proceed to speak of the peculiarities presented by the disease as it affects different regions of the body.

1st. *Eczema of the hairy scalp* (*teigne muqueuse*, Alibert; *porrigo larvalis*, Willan). Extremely frequent among children at the breast, of three, five, and eight months old, and at the period of the second teething, it not uncommonly attacks young persons of both sexes, especially such as have fair hair and a fine and delicate complexion, with a scrofulous taint and lymphatic constitution. This variety, which has been separated erroneously from the group of eczemas, and variously placed among the *tineas* and *porrigos*, appears at one time on a portion, and at another invades the whole surface of the scalp, extending occasionally even to the ears, nape of the neck, forehead and face. In very young infants the vesicles of this eczema spread over the scalp and temples, and soon become covered with thin scabs that increase in thickness as the exudation continues. The swollen hairy scalp, indeed, pours out a profusion of a viscid fluid which glues the hair into masses or layers, and in drying, forms yellow or brown lamellar incrustations. In this acute state the head is hot, and the scalp appears injected and tense; children are then tormented with a pruritus of the affected parts, the violence of which cannot be expressed by words, and which seems to gain in intensity when their heads are uncovered and exposed to the air; they rub them violently upon their shoulders, and, if their hands be at liberty, they scratch themselves with the greatest imaginable eagerness, though the blood constantly follows the nail.

When the hair has been cropped with care, and the scabs got rid of by means of emollient poultices, the hairy scalp appears to be covered with a sort of cheesy matter. Occasionally the inflammation extends to the subcutaneous cellular membrane, which forms small prominent tumours attended with very severe pain, usually ending in suppuration. The lymphatic glands of the nucha and parotid regions swell and grow painful. In some cases the vesicles of the eczema are mixed with the pustules of impetigo, and the incrustations formed are then much thicker and more adherent than wont. An immense quantity of pediculi usually appear on the scalp at the same time.

Eczema of the hairy scalp often extends to the forehead, temples, face, nape of the neck and shoulders.

If the children attacked with this disease be carefully attended to, if the incrustations be gently removed by means of lotions and soothing cataplasms, the inflammation of the scalp declines, and the exudation from its surface usually ceases within one or two months at farthest. If these measures be neglected, the caps and other articles applied to the head become impregnated with the fluid secreted by the inflamed surface and increase the pruritus; the inflammation becomes chronic, and extends more deeply; the bulbs of the hair inflame, and often cease from their functions over a considerable extent of surface; the scalp at the same time assumes a furfuraceous appearance on some of the inflamed points (*teigne furfuracée*, Alibert).

When the ichorous exudation ceases suddenly, either naturally, or in consequence of ill-timed medication, and the incrustations grow hard and friable, children become dejected, taciturn, restless and evidently unwell. On the other hand, when the exudation is very abundant, the principal functions are frequently performed with the most perfect regularity, and the health of the little patients seem occasionally even to improve during the whole period that the disease continues. I shall add further, that those children who labour under eczema of the face and hairy scalp whilst they are teething, rarely suffer from convulsions or obstinate diarrhoeas. This remark is in accordance with the result of M. Billard's observations, who tells us that, at the Foundling Hospital of Paris, he noticed a considerable

number of infants at the breast attacked with eczema of the scalp (*teigne muqueuse*), who, after the slow and natural cure of the disease, were remarkable for the freshness of their colour, and their excellent state of health. Among adults, *chronic* eczema of the scalp seizes particularly on individuals of a lymphatic and scrofulous habit of body. Women at the critical period of their lives are more frequently attacked than men. The greater number of these cases of eczema, *humid* and *secreting* at first, become at a later period *squamous* and *furfuraceous*; the swelling, redness and heat of surface are then almost wanting, and the scalp freed from the squamæ that covered it, appears somewhat red and shining. The squamæ are occasionally of a silvery and pearly lustre, and very much resemble the pellicles that envelop the sprouting feathers of young birds. Occasionally tufts of five or six hairs are bound together, as it were, at a short distance from their roots and free ends by these squamæ. In this state the disease is not accompanied by any great degree of itchiness, and the head has no particular odour.

Chronic eczema of the scalp now and then spreads to the ears and eyebrows; it also occasionally attacks the margins of the eyelids, causing the fall of the eyelashes, and a chronic ophthalmia of a very intractable description.

Eczema of the hairy scalp is a disease that is very rarely met with among the aged, in consequence probably of the alterations that have taken place in the organization of the skin. I have oftener than once seen the disease coincide with a more than usually copious secretion of cerumen. (a)

2d. *Eczema of the face*. In young children eczema of the face often accompanies that of the hairy scalp and of the ears; many authors have described the affection under the title of *crusta lactea*. It usually appears on the forehead, the cheeks and the chin; the small vesicles that characterize it, are arranged in irregular clusters, and scarcely rise above the level of the skin, which soon assumes an erythematous blush; within four or five days these vesicles burst, and pour out a viscid and yellowish fluid which concretes and turns into thin yellowish-green coloured scabs; fresh vesicles are before long developed around the circumference or in the immediate neighbourhood of these clusters; the fluid they contain is shed on the surface of the skin, at the same time that a considerable exudation takes place below the first formed squamæ or scabs, which adds farther to their thickness and extent. If this disease be left to itself many eruptions occur one after another, until the whole countenance is covered with yellowish laminated incrustations. The serous or sero-purulent fluid secreted, is often very copiously shed under the laminae and scabs; the skin is of a vivid red, and appears beset with a multitude of minute pores which are covered with slight false membranes of a milky white colour; it becomes chapped and excoriated on the cheeks, at the angles of the mouth, and in the furrow between the lips and the chin, and these tender places are all made worse by the act of sucking, crying, and the contact of the tears; the disease in this state has all the distinguishing features of *eczema impetiginodes*. At a still more advanced period, eczema of the face presents all the characters of a chronic inflammation; the vesicles are few, the discharge becomes smaller in quantity, ceases at length, and the skin is endued with dry and grayish-coloured scabs, which are thrown off without being reproduced; the diseased surfaces, covered with a cuticle of extreme tenuity, continue long to show an erythematous

(a) "Of the diseases of the scalp which I have been called upon to treat during the last twenty-eight months, amounting to above 280 cases, more than 180 were cases of eczema; seven were cases of herpes; sixty-five were cases of impetigo; six were pityriasis; eight were cases of psoriasis, or lepra; and eleven only were cases of porrigo. From inquiries I have made among persons whose opportunities of observation have been favourable, I am inclined to think that the proportion shown in my own experience is about that which is usually observed. It is true that now and then the proportion would seem to be different; but the variance is unquestionably owing to particular circumstances. Porrigo has broken out in a school or a family, and has been rapidly communicated by contagion, so as to swell the proportion of the latter disease." (Mr. Phillip's Lect. on surgery, in Med. Gaz., 1840.)

blush, and are then affected with a furfuraceous desquamation, which also ceases at last. The excoriations and fissures which attend eczema of the face never leave cicatrices behind them. Those that do occasionally remain are effects of the wounds which children inflict on themselves with their nails; to prevent them from doing mischief, therefore, it is proper to confine their hands during the night, for without this precaution I have seen many who made their faces bleed with scratching.

Eczema of the face sometimes spreads to the margins of the eyelids, to the mucous membrane of the mouth and nasal fossæ, and to the conjunctivæ; the epithelium, where it exists, is rapidly destroyed, and is replaced by small patches of whitish false membrane. When the eczema of the eyelids extends to the conjunctivæ we have all the symptoms of acute ophthalmia: the eyes become red and injected, watery, and sensible to light; the free edges of the eyelids are swollen and cedematous. When eczema occurs in the nasal fossæ, it causes a very troublesome sense of itching, and a very copious flow of a serous fluid. This disease seldom attacks the mouth; I have seen it confined to the under lip, round which it formed a kind of ring; it happens occasionally that the mucous membrane of the mouth, which appears to be generally red and swollen, presents here and there small superficial ulcers like aphthæ, and children then excrete a great quantity of saliva.

In adults, *eczema rubrum* and *impetiginodes* of the face are often attended by a general swelling of the features, and an œdema of the eyelids similar to that which is observed in phlegmonous erysipelas. Eczema of the face differs from this form of inflammation by being essentially a disease of long continuance, and by the skin, instead of exhibiting a simple exanthematous inflammation complicated with occasional phlyctenæ, presenting a vesicular, or a vesiculo-pustular eruption, generally accompanied with a severe itchy heat of the surfaces affected. When eczema of the face has passed to the chronic state, the serous exudation is almost insensible, the face becomes covered with bran-like scales, which fall off, and are renewed repeatedly; the eyebrows and eyelids now and then lose their hairs. I have seen this variety, which is very intractable, more especially in young girls of a lymphatic temperament, whose menstrual discharge is irregular, or in whom this evacuation is not yet established. It is very seldom seen among the aged.

3d. *Eczema aurium*.—This is one of the varieties most commonly met with in the two sexes at all ages. It often occurs to women at the period of the menstrual cessation. Lorry has specified its characters accurately (*de auribus suppurantibus*). Infants are attacked with the disease at a very early age; and it frequently coincides with eczema of the scalp, or face, the development of which it occasionally precedes or follows. It must not be confounded with intertrigo, a kind of erythema of the posterior parts of the ears, attended with chapping, and some slight exudation. I have also seen many cases of this affection among young women from fifteen to twenty years of age, who either had not yet menstruated, or who had menstruated very irregularly. When this eczema appears with the acute character, the ears become red and swelled to such a degree that their size is often doubled; a reddish fluid flows rapidly from the vesicles, chaps and fissures are formed, and the inflammation is propagated to the meatus auditorius, around which small purulent abscesses are occasionally formed that prove excessively painful. The sense of hearing is either perverted or lost for a time; the lymphatic glands in the vicinity swell. This eczema most usually becomes chronic; the skin is covered with lamellæ of a deep yellow colour, very similar to cracked strata of yellow bees-wax; a reddish fluid, the flow of which is increased by pressure, exudes from the fissures. Often, when the diseased parts appear to be returning to their natural state, all at once and without known cause, a new eruption appears.

Eczema of the ears is usually a very obstinate disease when it attacks females at the critical age; it gets well, on the contrary, readily and naturally in children, when it has broken out during the process of teething. Pieces of sponge or tents of lint have by some been recommended to be placed in the meatus auditorius to prevent the contraction of this passage; but the precaution has more inconveniences than advantages. When the eczema is acute in its character, more good is done by blood-letting, the application of leeches, and the

use of pediluvia and aperients; and when the disease is of a chronic nature, the swelling of the subcutaneous cellular membrane seldom goes so far as to make any precaution of the kind mentioned necessary. It rarely happens that eczema of the ears does not extend to the parotid regions and hairy scalp; the two ears are also most commonly affected at the same time; but the disease seldom attains the same degree of severity in both.

4th. *Eczema mamillarum*.—Eczema of the nipple is a much more uncommon disease than the varieties I have hitherto described; I have never met with it in young children. M. Levain has collected several cases of its occurrence in young women who were nursing for the first time. It is of consequence not to confound this affection with erythema and chapping of the nipples, which are much more frequent complaints with young nurses. It is occasionally observed, especially in the chronic form, in young girls and grown women who have never given suck. The inflammation is at times transferred from one nipple to the other; very violent itching is felt, and a yellowish or reddish serum flows abundantly from the affected parts, and rapidly penetrates any dressing that may be applied. The mucous membrane of the nipple, inflamed over its entire surface, although in an unequal manner, presents small excoriations like linear scratches; some points are of a bright red, moist, studded with sero-sanguinolent drops; others are covered with yellowish scabs, which are thick in the middle, and decrease towards their circumference. This complaint is usually attended with severe pruritus, which increases on the approach and during the continuance of menstruation. The nipples remain scaly for a long time after the inflammation has subsided: they are moist and exuding one day, dry and scaly the next. At length, after many recoveries and as many relapses, the pruritus ceases, the serous exudation appears no more, and the parts are covered with a new epithelium, smooth and uniform like that which covers the healthy surface. I have never observed eczema of the nipple in the male. It is important, as I have already said, to distinguish eczema of the nipple from simple chapping or cracking of the part; and above all, not to mistake it for a syphilitic affection; it is usually very intractable, may continue for years, and requires active treatment on its first invasion.

5th. *Eczema umbilicalis*.—The skin of the umbilical region bears great affinity to that which surrounds the natural openings. Eczema of the umbilicus consequently very much resembles that of the nipple and vulva. It has been mistaken for a syphilitic blenorrhœa. In newly-born infants, the pulling which the cord has undergone, the ligature of this part and the use of unguents, give rise now and then to the development of minute vesicles and to slight excoriations, distinguished from those of true eczema by their short continuance.

6th. *Eczema of the insides of the thighs, prepuce, scrotum, verge of the anus, and lower end of the rectum in the male*.—These varieties of eczema are all very rare in early life; they are more frequently met with between the thirtieth and fortieth year than at any other age. The eczema may begin in any one of these regions, and then creep on to the others in succession, or else attack them all at the same time. The sleep is broken; tormented by incessant pruritus, the patients become restless and irascible; the vesicles either break or are violently torn at the moment of their formation, so that it is often impossible to find a single one untouched; the skin is bedewed with an ichorous fluid; the patients tear themselves with their nails; crevices are formed from which a sero-sanguinolent exudation takes place; the penis, scrotum and perineum are extensively excoriated; the lint and dressings applied to these parts are speedily soaked with discharge; walking, and the friction of the clothes, the heat of the bed, and occasionally the presence of pediculi, add to the amount of irritation, which is already excessive; erections, and the act of emptying the bladder and rectum, are often attended with pain. In the great majority of cases, this form of eczema becomes chronic. It proves at all times a protracted and obstinate disease, and one in which patients are willing and eager to submit to the most energetic treatment, in order to get rid of their misery; there are cases, however, in which this ought to be employed with great discretion. One of my patients, who had laboured under a chronic eczema of the margin of the anus for twenty years, became accidentally affected with a very severe inflammation of the gastric and pulmonary mucous membrane, which yielded to a rigid adherence to low diet, the use of asses' milk,

mucilaginous diluents, and the insertion of an issue. During the acute and most severe period of this disease, the eczema of the fundament disappeared completely, but broke out again after the cure of the gastro-pulmonary inflammation. This interchange of internal and external inflammations is well worthy of engaging the attention of the pathologist and therapist.

Eczema of the scrotum, perineum, &c., and especially the fissures it occasions in the skin, have occasionally been confounded with lichen *agrius* and syphilitic sores.

7th. *Eczema of the inner parts of the thighs, of the vulva, of the verge of the anus, and of the mucous membrane of the vagina and rectum in the female.*—Children are seldom attacked with eczema of these regions. In the adult female the disease may commence in any one of them and be propagated successively to the others; or it may seize on all of them at once. Like the disease in the male it begins with heat and intolerable itching; the vesicles burst as soon as formed; the pain becomes unbearable, excoriations take place, the disease spreads to the labia majora, to the mucous membrane of the vagina, to the verge of the anus and to the rectum. The scalding heat and pruritus are extremely violent; the passage of the urine is painful; a discharge of an offensive smell takes place from the external organs of generation. The vagina and inner surface of the labia present slight superficial excoriations; patients occasionally addict themselves to masturbation with a sort of fury as in prurigo *pudendi*; the sexual act is either impossible or exceedingly painful.

This variety of eczema has been sometimes taken for a syphilitic affection; and it is often difficult, when it is accompanied with a leucorrhœal discharge, to determine whether this flux be the cause or the effect of the vesicular eruption. Discharges from the vagina, however, give rise much more frequently to intertrigos than to true eczemas.

8th. *Eczema of the upper and lower extremities.*—Eczema of the forearm, of the arm and of the thigh present nothing peculiar; those of the legs, in elderly persons, have been described under the title of *tettery sores* (*dartres ulcereuses*). They usually begin in a chronic form, and are occasionally accompanied with varices of the veins and with ulcers. Eczema of the legs often presents the characters of eczema *rubrum*. The skin, of a livid hue, tense, not very hot, and sprinkled with numerous pores that pour out an ichorous reddish fluid, presents excoriations of a bright red, the surface of which is dotted over with points of a deeper shade of the same hue; other parts present yellowish laminated incrustations, fissures or extensive excoriations. The vesicles are very rarely to be seen entire. The eruption is occasionally propagated to the dorsal aspect of the feet, to the toes and the integuments between them, and then the same phenomena are observed as when the disease attacks the hands and fingers. Farther, it is requisite to distinguish a primary form of eczema followed by sores, from those vesicular eruptions that are produced by the contact of discharges from ulcers of an older date. The cure of these eczemas is accomplished with difficulty; and even when the excoriated places are healed up, when the serous exudation no longer takes place, and the fall of the scabs has been completed, an epidermic exfoliation and scaly state of the skin continue for a long period; the skin too retains a reddish, livid and shining appearance, and the slightest irritation brings back the disease in greater severity than it possessed even on the first invasion.

9th. *Eczema of the bend of the arm, of the axillæ and hams.*—These varieties, in their evolution and in their progress, have a great resemblance to those that appear about the margin of the anus and vicinity of the genital organs in either sex; they are, however, much less painful. Those of the axillæ are the most uncommon, and have frequently the appearance of the eczema *impetiginodes*. In these regions the heat is usually considerable; they are in an habitual state of moisture; the follicles are numerous, and the motion of the parts incessant: hence the violence of the pruritus, the copious discharge of serous fluids, and the occurrence of excoriations and chaps so difficult to cure. It is important to distinguish these varieties from confluent lichens.

10th. *Eczema of the hands.*—Eczema *simplex* occasionally appears between the fingers, on the backs of the hands and on the anterior parts of the wrists. I have seen the vesicles of this disease as large and as pointed as those of scabies, so that it was matter of difficulty

to distinguish between them. It is true that one of these affections is contagious and the other is not; but the experiment that must be made to establish this diversity of character cannot, of course, be recommended to be instituted on purpose. Eczema *rubrum* very frequently occurs on the backs of the hands and fingers; occasionally between the fingers and around the nails; the vesicles being extremely crowded in these cases may give rise to the formation of bullæ of various dimensions. When confined to the circumference of the nails, as I have several times seen the disease, it simulates onychia very closely; and when it gets chronic in its nature, the skin on the backs of the hands becomes covered with large thick scabs of a yellow or brown colour, and the spaces between the fingers present deep fissures, the bottoms of which are highly inflamed, whilst their edges are covered with laminated scabs. From these fissures a seropurulent fluid is continually exuding, especially when the parts are bent, or used in any way. When the hand is passed over the diseased surfaces, they appear as rugged as the bark of an aged oak. Long after the disease is to all appearance cured, the skin remains hard, dry and scaly, and is very liable to chap and split.

In general eczema, after several successive crops of eruption have been evolved, the inflammation occasionally spreads to the palms of the hands. The fluids effused are then detained under the thickened cuticle, and not shed upon the surface, a circumstance that modifies the appearance of the eruption notably.

Eczema of the nails will be described in another place. See Onychia.

350. *Complications.*—The numerous cases which I have watched myself through all their stages, prove that eczema may co-exist with the greater number of the diseases that attack the external integuments. Pustules of impetigo are very commonly seen in the middle or near vicinity of a district attacked with eczema; this is even the most natural, as it is the most frequent complication. I have seen eczema coincident with lepra. The vesicles were disseminated in the intervals between the scaly patches, and got well, whilst the leprosy continued unchanged; as if these different affections had severally depended on some peculiar and distinct condition of the system. I have seen a young woman labouring under very extensive psoriasis *guttata* and a moist eczema of the face and ears at the same time. I have observed eczema co-existing with scaly syphilitic affections. The bullæ of rupia, the pustules of ecthyma, and boils are occasionally observed in individuals labouring under chronic eczema of different districts of the body. Certain forms of eczema of the sexual organs and hairy scalp are attended with the production of pediculi, which incessantly excite the patients to scratch themselves. Eczema is occasionally observed to precede scabies; at other times it seems to be induced by the unguents employed in the treatment of this disease.

Among children, inflammatory affections of the mucous membranes frequently coincide, or alternate with the development of this eruption. When it is general, and the secretion is abundant and continues long, cough and diarrhœa are apt to supervene, especially among the aged, and individuals weakened or worn out by previous disease. I have seen eczema of the scalp, ears and face spread to the mucous membranes of the eyes, meatus auditorius and nostrils, causing intense ophthalmia, severe otitis, and chronic coryza followed by profuse and fetid discharges. Pregnancy may cause the development of eczema, and complicate or stand in the way of its proper treatment; occasionally, also, the disease has appeared in nurses, as a consequence of weaning. Among children it now and then appears on the mucous membrane of the mouth. Eczema of the legs in old people is rather frequently accompanied with the appearance of petechiæ around the inflamed parts of the skin, also with œdema, varicose tumours, and ulcers which protract or impede its cure. I have seldom seen eczema occur among the consumptive; on the other hand it frequently coincides with gastric, enteric and bronchial inflammations, especially among children, in whom it is often replaced by convulsions. The practical inferences to be deduced from these observations are, that the treatment of eczema is to be modified according to the ages and the idiosyncrasies of individuals, and above all, according to the nature and the intensity of its different complications.

351. *Alterations of structure.* The follicles of the skin are the parts essentially affected in eczema. And we observe, in fact, that if the disease may and does attack almost every district of the integuments, it shows itself in preference on the inside of the thigh, at the bend of the arm, in the hams, the axillæ, the groin, on the scrotum, labia, margin of the anus, and generally in those situations in which the follicles are the most largely developed, and the most numerous bestowed. The disease is very frequent in the scalp among children, and there, in early life, the follicles are very numerous and very large; in this situation, on the contrary, it is rarely met with among the aged. Farther, the disease seldom appears in districts where the existence of follicles is matter of doubt, as in the palms of the hands and soles of the feet, the neighbourhood of the patellæ and olecrana. And to conclude, in eczema *simplex* the affection of the follicles is evident to the eye. In eczema *simplex* the papillary body does not appear to be injected; it is so, however, in the variety entitled *rubrum*, in which the deep layers of the corion and the subcutaneous cellular tissue are also occasionally inflamed. When excoriated, the skin may become covered with pseudo-membranous deposits, analogous to those which are observed on blistered surfaces. I have even seen the skin of the leg, in old subjects labouring under eczema *rubrum*, presenting small holes which might have been filled with the head of a pin, and little sinuous ulcers, very irregular in their course, which did not interest the whole thickness of the corion; the skin had an appearance very similar to that which a piece of mahogany board worm-eaten on its surface might be supposed to present. In chronic impetiginous eczema I have noticed small nipple-like projections on the surface of the skin which were owing to a sort of elongation of the natural papillæ. The cuticle itself undergoes various alterations in this disease. In the chronic forms it is resolved into a kind of farinaceous dust, or is thrown off in little laminæ, the centres of which, of a yellowish-gray colour, are more adherent than their circumferences. In certain eczemas of the hands the cuticle becomes dry and falls off in large yellow scales which are thick in proportion as they have been infiltrated with diseased secretions. Lastly, the cuticle is entirely destroyed in certain cases, and the corion is either exposed or is covered by incrustations of various thicknesses. The fluid secreted by the diseased surfaces, serous, limpid and almost inodorous in one case, is turbid, yellowish or greenish, and more or less consistent in another; it has a faint and sickly smell in eczema *impetiginodes*, especially when pustules of impetigo occur mingled with the vesicles of the eczema. In drying, this secretion gives rise to the formation of scabs which have some resemblance to those of impetigo. When the inflammation runs high, it may implicate the bulbs of the hair and the matrix of the nails, and cause these appendages of the skin to be detached. In brief the primary seat of eczema is in the follicles of the skin; but other elements of this tissue are affected in eczema *rubrum* and *impetiginodes*. The papillæ, the entire thickness of the dermis, the subcutaneous cellular membrane and the lymphatic glands are occasionally affected one after the other: hence those small abscesses that form in children who are attacked with eczema of the head, and those painful inflammatory swellings of the glands which occasionally end in suppuration. Other diseases of the skin (acne, rosacea, mentagra, and impetigo), also affect, and, indeed, more evidently affect the follicles than eczema. There are consequently essential differences between the various diseases of the skin which must be sought for elsewhere than in the immediate affection of the several anatomical elements of which this tissue is composed.

352. *Causes.*—I have met with several cases of eczema that appeared exclusively during the period of uterine gestation, that yielded with this state, that returned in a second and third pregnancy, and got well immediately after delivery, although various plans of treatment had been vainly tried before this event. Among children the process of teething and the quality of the nurse's milk, among women the states of amenorrhœa and dysmenorrhœa frequently exert a notable influence upon the development of eczema.

Our inability in a multitude of cases to discover any evident, or even probable cause of the disease, often leads us forcibly to the conclusion that eczema is most generally evolved and kept up by some hidden alteration of the fluids and solids. In this disease, as in

almost all inflammatory affections, independent of external causes, the blood is buffy.

If a patient who has recovered from one attack of eczema is seized a second time, it is almost certain that the disease will be of the same genus and species as before. This speciality in the form, and probably in the nature of relapses, has been observed in pemphigus, in favus, and in several other diseases of the skin.

In infancy and youth, eczema appears more particularly on the head; in riper years on the breast and belly, but especially on the genital organs; and in advanced life, on the lower extremities and about the margin of the anus. According to Billard, eczema is also frequently observed on the trunk and extremities of the newly-born infant; he tells us he has seen the disease in infants scarcely a day old. M. Levain having delivered a woman labouring under impetiginous eczema of the whole body, observed that the child two days afterwards presented several clusters of vesicles on the left forearm, on the neck, and in the hams, and by and by eczema *rubrum* appeared on the forehead and hairy scalp. It is at the periods of the first and second dentition that children are more especially attacked with eczema. Women are more subject to the disease than men, particularly at the critical period of life. Chronic eczemas of the hairy scalp, ears, eyebrows, and eyelids, are common in scrofulous subjects. Eczema is not a contagious disease, but under certain circumstances, especially when the discharge is copious, the contact of the secretion may determine vesicular eruptions upon healthy parts. M. Levain has seen acute eczema of the labia in a woman whose husband had long laboured under a similar eruption of the scrotum; the woman in this case had a rapid recovery. I have collected several cases of the same kind.

Relapses are observed to happen in almost all diseases, but in none are they more frequent than in eczema. I have collected many instances of unlooked-for returns of the complaint in consequence of variations of atmospheric temperature, errors of diet, affections of the mind, &c. I have seen the disease get well and recur twelve or fourteen times within the space of a few months, in despite of the most scrupulous and undeviating attention to regimen. These relapses happen particularly among individuals of an irritable and nervous constitution.

353. *Diagnosis.*—Eczema is of all the diseases of the skin that which presents the greatest variety in its appearance, for as it is acute or chronic, simple and unmixed, or complicated with pustules, it may be characterized by vesicles with or without redness, by moist or running excoriations, by laminated incrustations, or by small furfureaceous scales.

Willan and Bateman have both connected to the group of eczemas several artificial or accidental vesicular eruptions, which both in their nature and means of cure are totally distinct. Such is the *sun-fret* (eczema *solare* of these authors), which is observed among labourers in the time of harvest, and the inhabitants of towns who flock into the country during the fine season of the year. The skin of the face, neck, hands, and other parts usually left uncovered, is attacked with erythema, to which succeeds a plentiful eruption of vesicles, analogous indeed in appearance to those of eczema, but speedily ending in a slight furfureaceous desquamation of the cuticle.

Some preparations of mercury excite a vesicular eruption which has been connected with eczema, and which resembles this disease considerably in its external characters; but in its nature and progress it bears a much nearer affinity to inflammations artificially produced.<sup>1</sup> Various other substances, such as Burgundy pitch, adhesive strap, plasters of cicuta and opium, the juices of certain plants of the family of euphorbiaceæ, the oil of the croton tiglium, sulphureous lotions, diluted acids, &c., have also the property of causing minute vesicles to be developed on the skin, which in their form, arrangement and size approach more or less nearly to the eczemas. All these vesicular inflammations, however, differ essentially from this group in their nature, and get well with an ease and a rapidity that make a strong contrast with the inveteracy and tendency to return of eczema.

The vesicles of herpes are globular, and arranged in clusters surrounded by an inflammatory areola, of much greater extent than that

<sup>1</sup> Vide sub. Hydrargyria.

of eczema. The minute serous vesicles that are occasionally observed along with rheumatic affections, puerperal peritonitis, the furuncular disease of the bowels (dothineritis), &c., are devoid of inflammatory characters, and are very different from the vesicles of eczema.<sup>1</sup>

When eczema *simplex* appears between the fingers, on the wrists, bends of the arms, hams, and fore parts of the belly, it is at times difficult to distinguish it from scabies: it was a mistake to say that the vesicles of eczema were always flat and agglomerated. I have seen them as large as those of scabies, dispersed and separate like them, and like them, too, a little pointed: but scabies is essentially contagious, eczema is not; this is almost always acute, that as constantly chronic in its nature; the pruritus of eczema is accompanied with a kind of smarting, that of scabies is rather a pleasant than a painful sensation.<sup>2</sup> The small, red, solid and itchy papulæ of lichen do not contain any serum like the vesicles of eczema *simplex*. In confluent and inflamed lichen (lichen *agrius*, Willan), when the papulæ, crowded together in large patches have been torn by the nails, the skin, in a raw and bleeding state, pours out a sero-sanguinolent fluid which, in drying, assumes an appearance intermediate between squamæ and scabs, that might readily cause the disease to be mistaken for eczema *rubrum*. This advanced and very severe form of lichen has consequently been approximated by M. Alibert to the excoriations of eczema, and mixed up with his description of the *Dartre squameuse humide*. The small psudaceous pustules of impetigo, from their very first appearance, contain a thick, greenish-yellow fluid. Eczema *impetiginodes* in its commencement either presents transparent vesicles which become rapidly purulent, or, more rarely, a mixture of the proper vesicles of eczema and of the pustules of impetigo. The scabs of eczema *impetiginodes* are not so thick, but drier, and more compact than those that follow the rupture of the pustules of impetigo, the scabs of which are of a greenish-yellow colour, rough and uneven aspect, and not very unlike the masses of gum that concrete upon the cherry-tree. Eczema of the labia and vagina causes a discharge that might be mistaken for a gonorrhœa; it is rare, however, that a few untouched vesicles may not be discovered in the neighbourhood of the affected parts to serve as guides in the diagnosis. (a)

(a) The following contrasted characters, given by Mr. Phillips, (*Lect. on Surgery, Med. Gaz.*, 1840,) will aid the student in the diagnosis of eczema: "As you see, it would not be difficult to mistake these affections for scabies. Like it they are often developed without inflammation—like it they often affect the wrists and sides of the fingers—like it, they produce great itching; but, then, the vesicles of eczema are flat, those of scabies are conical-acuminate: those of eczema are agglomerated, those of scabies are distinct and isolated. The itching of eczema is stinging, that of scabies is rather an agreeable sensation. Scabies is essentially contagious; eczema is either not at all, or very little so. Eczema *rubrum* sometimes bears a resemblance to miliaria; but, then, in miliaria the vesicles are never confluent—they are larger, and there is more general excitement. The eczema *impetiginodes* can scarcely be mistaken for impetigo: the surface occupied is usually large. Impetigo pustules never, at their commencement, contain a transparent serum; they have a large base, and a thicker fluid. Eczema is, at first, always vesicular, and never contains true pus, but a yellowish sero-purulent fluid. Then, impetigo produces true thick scabs, yellowish and rugous; in eczema we see only thin squamæ. When the disease is chronic, it may be confounded with lichen. For instance, here is lichen *agrius*; it is accompanied by an exhalation of serum, followed by scales; but they are larger, thicker, yellower, than those of eczema. More like scabs, they do not leave after them a red, smooth, shining, or slightly excoriated surface, but a surface chagrined by small prominent points—papulæ; and, then, in lichen we can always find some papulæ, where eczema would present vesicles. However, where it occupies the hands, much attention is sometimes necessary. Again, it may be confounded with psoriasis. Here, again, the surrounding vesicles will be wanting. There may be no weeping; and, after the scales

The absence of pruritus in syphilitic affections distinguishes these sufficiently from the eczemas of the sexual organs, in which the itching is almost insufferable. It is occasionally difficult to discriminate between chronic eczemas grown scaly, and old lichens and prurigos, situated on the genital organs. Lorry appears to me, indeed, to have confounded these three obstinate forms of cutaneous affection in his description of *prurigo pudendi*; nevertheless, before falling into the chronic state, eczema of the genital organs is attended with a copious exudation which is never observed in the other diseases just mentioned. Eczema of the scalp in the state of desquamation is not always easily distinguished from psoriasis and pityriasis *capitis*; it is, however, seldom that no remains of yellowish incrustations and scabs, characteristic of this disease, are to be seen on any part of the scalp, or ears, or person at large, a circumstance never observed in pityriasis, a disease essentially furfuraceous and one that is never accompanied with a discharge.

354. *Prognosis*.—In children eczema of the scalp and face is often a salutary eruption. When it appears during the process of teething, it will hardly yield to treatment until the teeth have appeared. In young women whose menstrual function is irregular, eczema of the ears and scalp is an intractable malady, and seldom gives way before some favourable change is effected in the state of the general health. The disease is always subdued with difficulty in women arrived at the critical period of life; and when it appears during pregnancy it can rarely be subdued until after delivery. When eczema is hereditary the cure of the disease is very frequently followed by a relapse. Eczema of the hands among cooks, hat-makers, dyers, &c., is always difficult of cure. In elderly persons eczema of the legs, attended with œdema, and a varicose state of the veins, is often altogether incurable.

exfoliate, instead of a smooth, red, elevated surface, as is seen in psoriasis, we find a cracked one."

And again: "You have found a vesicle; the disease is vesicular; it must be, then, herpes or eczema: your first idea would be eczema, because for every single example of herpes, you will see from twenty to thirty cases of eczema. Herpes circinnatus is a circle, or, as it has been termed, a "ringworm"—eczema never so. Herpes only affects one or more points: eczema often the whole scalp; add to these the differential characters I formerly pointed out, and you can have no difficulty in making out the vesicular diseases which affect the scalp."

Of eczema *impetiginodes*, Dr. Carswell (*Clinical Lectures, Lancet* 1839), thus speaks: "And, in the first place, what are the elementary characters of eczema *impetiginodes*? This disease, as the term implies, is a compound of two diseases,—of eczema and of impetigo. Now, each of these, in its separate state, has its own elementary character—a vesicle in eczema, and a pustule in impetigo. In eczema *impetiginodes* we have both the vesicle and the pustule; the vesicle, however, being the primary element, and generally predominating during the early stage of the disease. And, besides, the pustular character of this affection always succeeds to the vesicular, and can easily be traced during its progress to a change in the contents of the vesicle, which consisting, at first, of a clear yellow-coloured serosity, afterwards becomes milky-looking, opaque, and puriform. In most cases, however, of eczema *impetiginodes* the pustular element is much less perfect than the vesicular, the contents of the former consisting of a sero-purulent rather than of a purulent fluid. But in cases in which the inflammation is more severe than usual, the perfect impetiginous pustule is formed; that is to say, the small, psudaceous pustule, characteristic of impetigo, and even the large or phylaceous pustule, characteristic of ecthyma.

"Such are the special and distinctive characters of eczema *impetiginodes*. The pustular character of this form of eczema distinguishes it from the other forms of the disease, viz., from the eczema *simplex*, which is a purely vesicular eruption, neither preceded nor accompanied by redness of the skin; and from eczema *rubrum*, which is always distinguishable by the bright red colour of the skin, and the number of minute vesicles by which it is covered. To distinguish eczema *impetiginodes* from some other diseases of the skin is not always so easily accomplished, and this is more especially the case in that form of scabies, called scabies purulenta, affecting the fingers and hands, parts, also, often affected with eczema *impetiginodes*."

<sup>1</sup> Vide sub. Sudamina.

<sup>2</sup> James the First of England and Sixth of Scotland, held that kings alone were worthy to have the itch, the pleasure of scratching was so supreme.—R. W.

Eczema resists curative means so much the more obstinately as it occupies a more extensive surface, as it is of older date, of a severer kind, and as it appears on the lower extremities or on the hairy scalp. When children and the aged are the subjects of eczema, it often proves a disease *which it is dangerous to cure*.

355. *Treatment*.—In calling to mind the influence which teething, amenorrhœa, dysmenorrhœa and pregnancy exercise on the production of certain eczemas, we are naturally led to the indications of cure. Some varieties of the disease get well in time under the influence of a regulated diet; others require means of greater potency; and there are a few which are either intractable, or which it would be dangerous to interfere with.

A considerable number of cures attributed to the use of medicines of little power, ought to be almost entirely ascribed to the influence of *regimen, rest and time*, which are frequently very powerful, especially among the poorer classes leading laborious lives, who are mostly admitted as patients into public hospitals.

I have seen children at the breast attacked with eczema of the hairy scalp who recovered by changing the nurse. I have seen many persons of mature years labouring under chronic eczema of the scrotum, verge of the anus and other parts, whose malady was constantly aggravated by the slightest irregularity in point of diet. It would be idle to ascribe too great an influence to the farrago of *cooling and cleansing* decoctions and drinks so constantly recommended in cutaneous affections, and especially in eczema; but, on the other hand, it is perhaps not going too far to affirm that, of late, these means, or rather the dietetic plans of which they formed a part, have been too much neglected. In no case, however, would it be reasonable to restrict individuals, otherwise in perfect health, to a lowering system of diet; their constitution might suffer from such a course.

I have met with several cases of eczema in which a vast variety of therapeutic agents had been fruitlessly employed, whilst the patients went on with their usual avocations, and took active exercise, but which were successfully attacked by the same remedies, from the moment that these individuals consented to *lay themselves up*. *Time* also modifies eczema at length, and occasionally accomplishes its cure; so that individuals labouring under the disease in a chronic form, have now and then got well without recurring to any medical treatment whatever.

The simple or emollient cold or tepid bath is frequently of the greatest service in the different acute species of eczema, even when the affected parts are not immersed in the water. In the decline of these diseases, when stiffness and dryness of the skin are alone complained of, and in the chronic eczematous affections of the backs of the hands, fingers, &c., the vapour bath, and, better still, the steam douche to these parts is found to be useful. When eczema has passed into the squamous state, the warm sea, and alkaline bath are efficient in freeing the skin from the layers of epidermis accumulated on its surface; but they almost always increase the redness, and the squamæ are rapidly reproduced. Local baths repeated several times a day, and fomentations of decoction of linseed, marshmallow flowers, poppy-heads, and milk, are often of advantage in eczema of the genital organs; in these cases the tepid hip-bath twice every day, always gives the greatest relief. If the disease have extended to the mucous membrane of the vulva, injections of althea-root decoction, with or without the addition of a little acetate of lead, are generally found to be soothing. Sulphureous baths have also been tried in the advanced stages of eczema, especially when the aged and enfeebled were the subjects of the disease. These occasionally cause new eruptions, and have been found effectual in restoring eczema, the disappearance of which, either spontaneously or obtained by art, has been followed by unpleasant or serious symptoms. The waters of the baths of Louÿsche have been frequently recommended with effect for this purpose. They have also occasionally seemed to make old standing eczemas run their course more rapidly, and thus to hasten their cure. I have seldom found artificial sulphureous baths produce such good effects, except in the chronic eczemas of elderly people, and some middle-aged persons, when they now and then seemed to lessen the redness and discharge from the skin, after having exasperated these morbid states for a time; scrofulous subjects alone received invariable advantage from the use of these baths. I have occasionally seen beneficial effects

from the use of a sulphureo-alkaline ointment. Sulphur exhibited internally has never seemed to me to exert any appreciable influence on chronic eczema, except when it acted as a purgative.

In running eczemas of small extent, emollient fomentations have been found of service. When the disease is followed by painful and extensive excoriations, and the skin is red and swollen, or covered by yellowish-looking scabs of considerable thickness, soothing-washes must be replaced by poultices of floury potatoes, of ground rice, and of crumb of bread, softened still farther with decoctions of althea and poppy-heads. These cataplasms are greatly preferable to such as are prepared of linseed meal, which are observed occasionally to induce artificial vesicular and even pustular eruptions. When the parts of the skin affected are covered with hair, these various topical applications must be used folded up in a fine muslin rag.

When poultices are employed in the treatment of children labouring under eczema of the hairy scalp and of the face, care must be taken to keep the head well covered, especially during the first few days, a precaution without which otitis and ophthalmia of greater or less severity are extremely apt to supervene. *Depilation* is an absurd and cruel practice during the acute period of eczema of the hairy scalp; neither is it ever to be recommended even when the inflammation has passed into the chronic state.

Moderate *compression* by means of a roller properly applied, is often employed with advantage in the cases of elderly persons affected with eczema *rubrum* of the lower extremities, when the disease is complicated with œdema or a varicose state of the veins, or when patients are obliged habitually to keep the erect posture without much motion.

Slight *escharotics*, solutions of the *nitrate of silver*, *diluted muriatic acid*, &c., have been recommended with a view to change the actions of the skin, when eczema has passed into the scaly state, and has continued for several months or years. With like intentions ointments of the *red precipitate*, of the lesser *celandine*, *clematis*, *spurge*, &c., and even *blisters* have been applied to the whole of the affected surface of the skin. If the cure of circumscribed chronic eczemas have occasionally been obtained by such means, these diseases have also been frequently and seriously aggravated by them. In general, when eczema has passed into the squamous or furfuraceous state, *soothing* ointments are the best local applications; the good effects of the ointments of oxide of zinc, and of the protochloride of mercury are certainly due in great part to the hog's-lard with which these substances are then largely incorporated.

M. Alibert has given the details of a case in which the disappearance of an eczematous eruption (*dartre squameuse*) was followed by insanity. I am in the habit of employing issues in obstinate eczema of the hairy scalp, and genital organs; and when we have succeeded in bringing about or are anxious to accomplish the cure of the eczemas of elderly persons, which have existed long, or of individuals who have previously suffered from a chronic affection of the viscera, it is advisable to institute and keep open an issue or a blister in one of the arms. If the theory of counter-irritation still requires clearing up, it is enough that by the practice we can relieve the mind of the patient especially, from doubts and fears, and therefore it ought not to be neglected.

I have said that eczema of the scalp, face and ears was occasionally a salutary disease in childhood. It is therefore proper to inquire in the first instance whether it might not be dangerous to attempt its cure; the best and safest termination being that which is accomplished naturally. Facts enough prove the danger of discussing these eruptions. On the other hand, inflammatory affections of the eyes, ears and viscera have been seen to disappear on the eruption of certain eczemas; in such cases it would be improper to attempt the cure of the cutaneous affection in any other than the slowest and most gradual manner. These remarks also apply to other ages, when the disease appears under similar circumstances.

The *vegetable acids*, diluted with water; sherbets of the *sulphuric* and *muriatic acid*, with or without the addition of gum; or milk mixed with barley-water or gruel, for those individuals with whom acid drinks do not agree, are usually recommended in the treatment of acute eczema. Such means are of less avail when the disease is chronic in its nature. When eczema is acute, and the pruritus is exceedingly troublesome, and the inflammation runs high, as in the

eczema rubrum or *impetiginodes*, it may be necessary to abstract blood once or oftener. I have had occasion to prove the utility of bleeding in a great number of cases, even of chronic eczema. When one bleeding has been followed by a notable improvement in the symptoms, it is commonly an inducement to repeat the operation after a few days have elapsed. I frequently make such experimental bleedings in the treatment of diseases of the skin. Cases of eczema, however, frequently occur, which resist this powerful means, or which even continue to advance in spite of its employment. It is, therefore, difficult to lay down precise rules for the management of every case, or to specify those in which blood-letting will be found serviceable or detrimental. It is almost always hurtful to individuals of an irritable constitution and spare habit, and in whom the cutaneous affection has supervened or been increased after some violent affection of the nervous system. Hereditary eczema is usually a very obstinate complaint, and we must beware of persisting in endeavours to effect its cure by means of blood-letting. In adults and individuals of mature years, the *general* is constantly to be preferred to the *local* abstraction of blood. The last is the only form of blood-letting that can be practised in regard to young children. In eczema of the face and scalp, of the pudenda and margin of the anus, a number of leeches are often applied with good effect in the neighbourhood of the affected parts. The aged bear bleeding badly; yet the measure occasionally becomes necessary when the parts implicated are severely excoriated and discharge abundantly, and when the disease is accompanied with violent pain and sleepless nights.

In chronic forms of eczema, especially affecting the scalp and face, the waters of Seidlitz and Balaruc, the sulphates of soda and magnesia, or the tartrate of potash administered so as to procure one or two liquid evacuations daily without inducing colic, or even exhibited in cathartic doses twice a week during two or three months, are found to be useful when they only cause a temporary state of irritation in the digestive passages, without exerting any lasting ill effect on the state of the general health. The use of these remedies must be immediately suspended when pain, a continual feeling of uneasiness, and febrile symptoms give us reason to fear the excitement of inflammation in the stomach or alimentary canal.

Purgatives are constantly had recourse to in the treatment of the eczemas of childhood. They are injurious to women who are pregnant or nursing. Individuals of a nervous temperament, and habitually confined in their bowels, always derive benefit from this class of medicines. Calomel alone, or in combination with jalap, is a good form of purgative; when prescribed in frequent small doses, however, its use is almost constantly followed by painful inflammation of the mouth. Eczema, in some of its forms, is so painful a disease, and causes such distressing insomnia, that recourse must often be had to medicines of a narcotic character.

Carrère and Bertrand-Lagrésie have greatly extolled the effects of the dulcamara in the treatment of eczema. The expressed juice, the decoction and the extract of this plant were prescribed by both of these practitioners, combined with purgatives, particularly a compound of the blue pill, with aloes, scammony and aromatics. After having fruitlessly tried the dietetic, the antiphlogistic and purgative plans of treatment in obstinate cases of eczema, about the verge of the anus and the genital organs, I have occasionally made successful use of the decoction of bitter-sweet, with the addition of a quarter of a grain of sublimate to each dose; but this practice has its dangers, or at all events its inconveniences, even when it is not pushed to extremes.

The preparations of arsenic are occasionally the only medicines which can be successfully administered in chronic and rebellious eczema of the scrotum, pudenda, verge of the anus, &c. I shall not repeat what I have already said, 188-192, of the *modus agendi* of this class of remedies, and of the precautions which are necessary to be observed in their administration. I shall only farther add, that the best advice which can often be given to patients advanced in life and of infirm constitution, is not to attempt the radical cure of such an infirmity as chronic eczema, if the disease be at all endurable. The removal of these natural drains of the system is often followed by serious symptoms of a different kind; or, if no ill consequence ensues, the cure seldom proves permanent, the disease generally

returning within a few months after the use of active medicine has been abandoned. (a)

#### *Historical Notices and particular Cases of the Disease.*

356. According to Ætius,<sup>1</sup> the Greeks characterized, under the name of *eczema*, those itchy vesicles that were not followed by ulceration. In later times Willan<sup>2</sup> restored the term, using it to designate a vesicular non-contagious eruption, various forms and different terminations of which had been improperly described as particular diseases under what were deemed appropriate titles.

Several cases of *eczema simplex* have been detailed under the names of *rubores cum vesiculis et pruritu*.<sup>3</sup>

An immense number of cases of *eczema rubrum*, *impetiginodes* and *fluens*, have been recorded by French pathological writers under the titles of *dartre vive*,<sup>4</sup> *dartre squameuse humide*,<sup>5</sup> *herpes fongueux*,<sup>6</sup> *dartre avec ampoules ou vesicules*,<sup>7</sup> and we must even arrange several descriptions of *scabies fera*,<sup>8</sup> and of *agria* under the single head of *eczema*.

Several cases of *eczemata* in their last and *furfuraceous* stage, have been described under the names of *dartre furfuracée*, and others under those of *dartre érysipélateuse* (*eczema rubrum*) and *milky eruption* (*eczema simplex*),<sup>9</sup> terms which correspond to the *running scall*, *humid tetter*, &c., of English writers.

*Eczemata* of the face and hairy scalp, in their acute states, have been described as *crusta lactea*,<sup>10</sup> *tinea mucosa*,<sup>11</sup> *porrigo larvalis*,<sup>12</sup> *scabies faciei*,<sup>13</sup> and *itch of the face and head of young children*:<sup>14</sup> the *scurfy* state and *asbestos* appearance of the dermis which this disease occasionally present in its last stage, have been described under the titles of *tinea furfuracea*,<sup>15</sup> and *tinea amiantacea*,<sup>16</sup> (*teigne furfuracée*, *teigne amiantacée*.)

Of late several cases of *eczema* have been published in different periodical publications.<sup>17</sup>

In the same works, also, may be found cases and remarks illustrative of the efficacy of the ointment of cantharides in restoring *eczematous* eruptions which had disappeared, and had been followed by ill effects, on the virtues of the *cicuta*,<sup>18</sup> on the inconveniences of oiled silk coverings in *eczemata* of the hairy scalp,<sup>19</sup> on the properties of the *diachylon gum plaster*,<sup>20</sup> of the *dulcamara*,<sup>21</sup> of *emollients*, and

(a) See, in a subsequent note, cases illustrative of the value of the arsenical treatment. In some of the more obstinate cases of chronic eczema, recourse may advantageously be had to Donovan's solution of the iodide of arsenic and mercury, in a dose of five drops gradually increased.

of *blood-letting*,<sup>1</sup> of the *white precipitate*,<sup>2</sup> of the *rhus radicans*,<sup>3</sup> of *lotions of sublimate*,<sup>4</sup> of the *sulphuret of potash*,<sup>5</sup> &c.

Poupart has given us several cases of recovery from affections, which he characterizes as *dartres vives* (eczema rubrum), which were followed by serious consequences of various kinds.<sup>6</sup>

The Essay of M. Levain, on the subject of the *eczemata*, is also deserving of a perusal.<sup>7</sup>

Confusion in the language employed, and in the arrangement of the facts observed, so conspicuous, has arisen not only from the discrepancies of our medical nomenclature, but also in some degree from the error into which the greater number of pathologists have fallen, of considering as distinct diseases the degrees and even the different terminations of eczema, the various modifications and successive transformations of which they had not studied with sufficient care. I regret that the nature of this work will not allow me to give a great number of particular cases of a disease the external phenomena of which are so varied, and whose treatment so frequently presents such insurmountable difficulties.

CASE XLIV.—*Chronic eczema of the right breast, cured by Seidlitz water and an alkaline liniment.* A young woman of a sanguine and lymphatic temperament had laboured under a chronic affection of the skin of the right breast for three months. Instead of being soft and pliant as in the natural state, the mucous covering of the nipple, and the neighbouring skin were covered over a space three inches in diameter, with grayish or yellowish epidermic laminae. Those towards the centre of the nipple were thicker than those in its circumference. The squamæ were furrowed with many superficial chaps, from which a reddish-coloured serous fluid exuded. No vesicles were to be discovered; these had all been destroyed. The patient stated that during the first stage of her disease the parts affected had poured out great quantities of *red water*. The nipple was the seat of rather violent pruritus, which became intolerable during the periods of menstruation. I recommended her to be purged once a week with a bottle of Seidlitz water, and the diseased surfaces to be anointed gently three or four times every day with a liniment composed of two parts of olive oil and one of lime-water, the quantity of the latter to be subsequently increased till it equaled that of the oil. The pruritus was notably lessened by a few applications of this mixture. After the fifteenth day of treatment it had entirely subsided, and within six weeks the cure was complete.

CASE XLV.—*Chronic eczema of both mammae; cure accomplished by the use of the ointment of red precipitate.* Mademoiselle N \* \* \*, nineteen years of age, of a sanguine temperament, applied at the fourth Parisian Dispensary, 21st November, 1825. Up to the beginning of this year the patient had enjoyed good health. At this period, however, she was attacked, without assignable cause, with eczema of the nipple of the right breast, and two months afterwards with the same affection of the corresponding part of the left breast. An abundance of reddish or yellowish-coloured serum flowed from the parts in the first instance; the local disease was unconnected with the slightest apparent derangement of the functions generally. For these complaints the patient had had recourse to a variety of remedies, general and topical, without deriving permanent relief from any one of them.

November 21st, 1825.—There is now no vesicle to be distinguished on the surface of the parts affected. The mucous covering of the nipples is entirely but unequally inflamed, and presents a number of small excoriations in the form of scratches and linear chaps. The epithelium is even destroyed in several places, which are of a very bright red colour, moist, and covered with minute points of blood. In several others it is thickened, and somewhat reddish: towards the circumference it is whitish and thinner. The surface of the nipple, in fine, bears a great resemblance to a blistered surface beginning to dry up which has been scratched, or, rather, the disease is in that state which has been so frequently designated under the title of *scaly*

tetter or *dartre squameuse* by the writers both of France and England. The surface of the nipple instead of being smooth and soft, is rough and uneven to the touch. The pruritus is at times unbearable; frequently, when the patient has successfully resisted the strong desire to scratch the affected parts through the day, during the night when half asleep, she tears the nipples with her nails. The inflammation is evidently superficial and does not extend to the subcutaneous cellular membrane. (*Diluted sulphuric acid, warm bath, Goulard's wash.*) These remedies were tried for a month without other advantage than a slight diminution in the inflammation. The acid was first omitted, and then discontinued from its having caused colicky pains of the bowels. The nipples continued squamous as before, discharging one day and becoming hard and dry the next. I now advised gentle frictions night and morning with the ointment of the red precipitate of mercury, to be discontinued should the nipples become very much irritated, and resumed when the state of excitement passed off. This plan was soon followed by the alleviation of the pruritus, the disappearance of the discharge, and the formation of a new epithelium, smooth and uniform as it is in a state of health. A relapse, however, occurred without any evident cause, and recourse was again had to the red precipitate salve. At length, after the cure had been apparently accomplished several times, and relapses, successively, however, of less severity, had happened as often, the eczema was finally and completely cured towards the latter end of March. The patient was kept on the books till the 4th of May, 1826, in order to be certain that no new relapse occurred.

CASE XLVI.—*Chronic eczema rubrum and impetiginodes of the left hand. Venesection, sublimate and dulcamara.* N \* \* \*, a straw-hat maker, thirty-six years of age, of a lymphatic constitution, consulted me in the month of February, 1822, on account of an impetiginous eczema of the left hand. The disease had appeared about three months previously, and in despite of a variety of remedial measures, had been growing continually worse. When I saw the patient first, the dorsum and metacarpal region of the left hand were painful, red, excoriated and pouring out abundantly from a great many places a viscid and very fetid ichor, so that dressings were speedily soaked and subsequently stiffened by the drying of the discharge. The patient had been obliged to discontinue her usual occupation five weeks back. Towards the circumference of the excoriation several small yellowish scabs, and a number of red patches appeared within the last few days, upon which a great many minute transparent vesicles were observed. Next day the majority of these vesicles were as large as pins' heads, and the fluid they contained was opaque and milky. Several small psudracious pustules, slightly prominent, and a few small transparent vesicles were thrown out on the sides of the fingers, the divisions between which were inflamed, excoriated and painfully chapped. The whole of these parts were affected with an intolerable pruritus, and the patient, in spite of herself, scratched them every instant. The patient's general health was good; the menstrual periods were regular. (*Venes. ad 3viii. Fomentations with decoction of bran, cataplasm of rice flour; a quarter of a grain of sublimate in a cup of milk every morning fasting; three glasses of the decoction of dulcamara daily, the tepid bath every fourth day.*) These measures were speedily followed by a decrease of the inflammation and of the morbid secretion which accompanied it; I was even tempted to think the cure at hand towards the end of the third week; the skin of the back of the hand was whitish and covered with squamæ, but it was without redness, chaps or discharge, and no new eruption either of vesicles or pustules had appeared upon the fingers. On a sudden, however, an eruption of vesicles took place over the same parts that had already been affected, accompanied during the first few days with a copious exudation and intolerable pruritus. The same plan of treatment was still pursued without apparent injury to the digestive organs; the new eruption ran through the periods more rapidly than the first; and by the 25th of March, 1822, the patient had completely recovered; nor has she had any relapse since this period.

CASE XLVII.—*Chronic eczema of both legs.* Madame \* \* \*, thirty-eight years of age, of a mixed sanguineous and nervous temperament, had never been particularly indisposed until she was attacked, without any assignable cause, with eczema of both her legs in the month

of March, 1822. After a violent sensation of smarting, tingling, and pruritus, a large red patch appeared on the outer part of the left leg, upon which with the naked eye, and better, with the aid of the magnifier, an innumerable quantity of minute vesicles were observed. On the following days several new spots, also covered with vesicles, made their appearance on the inner part of the leg, from the whole of which before long a yellowish and glutinous serum began to be discharged by an infinity of minute pores, in such abundance that every thing put about the limb was speedily saturated. The motions of the limb were performed with difficulty and pain, and the diseased surfaces were affected with pruritus of the most intolerable description. The right leg also became affected, but the vesicles here were much fewer in number, and the parts on which they were thrown out, inflamed in a much inferior degree. The general health of the patient was not deranged in the slightest degree. (*Venes. ad 3xii. ; the warm bath ; whey for drink.*) The legs were dressed with saturnine cerate spread on a perforated rag, with compresses of soft lint to absorb the discharge. These dressings and the medical treatment gave relief, so much the more remarkable as Madame \* \* \* had hitherto done nothing but apply fine linen and tissue paper to the inflamed skin, and the violence necessarily employed in changing these simple dressings had caused painful excoriations, from which drops of blood distilled every time they were renewed. The same plan of treatment was continued for two months, the disease at one time getting nearly well, at another becoming exasperated by the development of fresh crops of vesicles. The disease continued in this state for five months, the patient all the while leading the most regular life, and having used the warm-bath more than one hundred times, when at length it disappeared to return no more.

CASE XLVIII.—*Chronic eczema of the verge of the anus and of the scrotum ; psoriasis palmaris and plantaris ; various plans of treatment fruitlessly pursued ; cure obtained by arsenical preparations.* So long ago as the year 1805, N \* \* \* suffered from extreme itchiness of the inner parts of the thighs. In 1810 the disease had spread to the immediate vicinity of the anus, and surrounding parts of the buttocks. The lower part of the intestine at length became the seat of intolerable pruritus which occasioned the patient the greatest distress on going to stool. From the year 1822 the parts mentioned had the appearance of a kind of large open blister ; and the patient was compelled to go about with an abundance of lint between the buttocks, to absorb the scalding serum which was discharged from the inflamed surface of the skin. In 1824, the patient was attacked with large pustules on the arms similar to those of ecthyma, which only got well slowly and reluctantly. Towards the end of the same year, the scrotum became implicated in the first affection, and caused such excessive pruritus that the patient was continually tearing his skin with his nails ; a serous, yellow-coloured discharge exuded from an infinity of minute pores on the inflamed surface, upon which I was never able to detect any vesicles ; but the progress and the seat of the disease, as well as the copiousness of the discharge, induced me to regard this *scaly running tetter, this dartre squameuse humide*, rather as a chronic eczematous affection than as a lichen agrius, a presumption that was greatly strengthened by the existence of several small vesicles, similar to those of eczema on the inner and upper parts of the thighs. In addition to the chronic eczema, the patient was also attacked with psoriasis of the palms of the hands and soles of the feet. This new affection first appeared on the right hand between the thumb and forefinger, then on the palm of the left hand, and lastly on the soles of the feet. (*Gelativo-sulphureous baths ; three glasses of the decoction of dulcamara ; lotion with the alcoholic solution of corrosive sublimate, diluted ; soft lint between the buttocks.*) This treatment had produced some amendment within a few days. The vesicles on the inner parts of the thighs were touched with nitrate of silver and soon got well. Before a month had elapsed the inflammation of the scrotum, as well as that of the lower and posterior part of the raphe, had subdivided ; but the parts about the anus still continued red, slightly chapped, and discharging.

The inflammation having returned, the application of the oxide of zinc ointment was substituted for the lotion with the solution of corrosive sublimate. On the 18th of June the pruritus was excessively violent ; the compresses of lint were dipped in a lotion contain-

ing twenty-four drops of laudanum. The psoriasis of the hand was also worse. The patient called my attention to several fresh patches of a red colour on the palm of the left hand. These were neither covered with papulæ, vesicles, nor pustules ; the epidermis, over the parts of the skin affected, acquired a yellow colour ; at length, after the lapse of rather more than twenty days from the attack of the pruritus and heat, it split into fissures. June 29th.—No new vesicles have been evolved, but the skin of the upper and inner parts of the thighs is still red and inflamed. A fissure has taken place in the direction of the median line, and several phlyzacious pustules have appeared upon the upper part of the buttocks. They are as large as small boils, from which, however, they differ by being covered with a firmly adherent scab, and exhibiting no sign of a sloughy core in their centre. The psoriasis is better. The pruritus about the verge of the anus has increased, and seems to be excited by emollient fomentations. July 1st.—The patient complains loudly of the pruritus of the margin of the anus, which was excessively troublesome during the night. I applied the nitrate of silver to those points of the inflamed skin between the buttocks, which appeared to have lost their cuticle. Bathing the affected part with a solution of sublimate, having on former occasions given great relief, I recommended N \* \* \* to make use of a wash of this kind four or five times a day ; and with the same advantage as before. July 2d.—Five or six small round tubercles, which had existed for several weeks on the scrotum, terminated in suppuration. The patient was going on better, but from the 10th of July to the 15th of August, when he seemed to have completely recovered, he endured several unexpected and severe relapses. N \* \* \* now went to sea-bathing quarters, from whence he returned in the month of October, with the skin about the anus covered with squamæ. These were got rid of by steam douches to the parts several times a day, by which the skin regained its pliancy. Another relapse now induced me to propose arsenic to the patient, to the use of which he consented. On the 10th of November he began taking six drops of the solution of the arseniate of soda ;<sup>1</sup> the dose was gradually increased, and carried at last to the length of thirty-four drops. The medicine caused neither diarrhœa nor vomiting ; but on two or three occasions it excited shivering fits, a slight dry cough, and general uneasiness, which ought to have induced the patient to abandon it for a time. Up to the 15th of May, 1826, ten grains of the arseniate of soda had been taken, and the recovery was complete, at least in appearance, for the skin possessed its natural colour, and was covered by a smooth and supple epidermis, like that of the integuments in a state of health.

CASE XLIX.—*Chronic eczema of the hairy scalp, ears and cheeks, cured by the decoction of dulcamara, solution of corrosive sublimate, and oxide of zinc ointment.*—A. B., thirty years of age, asked my advice on account of an extensive eczematous affection of both ears, on the 5th February, 1826. This disease made its first appearance on the occipital region, after severe labour, and incessant watching during the illness of one of her children. A month afterwards it spread to the right ear, and from thence to the neighbouring regions ; the affected parts, according to the patient's report, had repeatedly discharged great quantities of a reddish fluid. This discharge ceased occasionally, and then returned more copiously than before. It was accompanied by intolerable pruritus. The patient's nights were sleepless, and she had lost flesh, but in other respects she was well. Feb. 5th.—The skin of the right side, affected with eczema, which has spread over the whole of the ear and a great part of the cheek, has a marbled and variegated and moist look, in one place exhibiting small red patches, where the corion is exposed ; in another, being covered with thin, yellow, laminated and strongly adherent scabs ; and in a third, having little points of blood scattered over an excoriated surface, amidst blackish incrustations which scarcely rise above the level of the integuments. The whole of this surface exhaled a sickly and very unpleasant odour, and a yellowish serous fluid exuded from the points which were most violently inflamed. On the left side, the cheek and ear were very similarly affected. Every part implicated was the seat of the most violent pruritus. No derangement of the digestive, nor of any other apparatus, could be detected. [Three

<sup>1</sup> This is the liqueur or solution de Pearson of French writers.—R. W.

glasses of decoction of *dulcamara*, and a spoonful of the liquor of *Van Swieten*, (a solution of sublimate, a quarter of a grain to the oz. of fluid) every morning, fasting.] These medicines were not taken without some inconveniences, which were relieved, however, by the use of the warm bath, and, at the end of a month, the disease had almost entirely disappeared; a few yellowish laminated crusts alone remained, which were soon thrown off, after a few applications of the oxide of zinc ointment. The cure in this case was completed without any relapse.

CASE L.—*Eczema of the hairy scalp (teigne muqueuse), with pediculi; subcutaneous abscess, gastro-enteritis: recovery under the use of the warm bath, local bleedings, and emollient applications.*—I was called to see a little boy, five years of age, on the 6th of January, 1826, the occipital region of whose head discharged a yellowish viscid fluid abundantly, which glued the hair together. I found the child affected with eczema of the scalp, and acute inflammation of the gastric and intestinal mucous surfaces. A straw-coloured fluid exuded from numerous points of the skin; other parts were covered with soft, yellow scabs, stuck amongst the hair. The head rested on the left shoulder; upon the occipital region several small subcutaneous phlegmonous tumours were detected by the touch, which were extremely painful. One of them, situated on the left side, near the mastoid process, being felt to fluctuate, was opened, and a tea-spoonful of laudable pus evacuated. A chain of inflamed and swollen lymphatic glands could be felt along the lateral and posterior parts of the neck. Rather acute pain in the epigastric region, occasional efforts to vomit, dotted redness of the tip, and whiteness of the base of the tongue, obstinate constipation, an accelerated pulse, heat and dryness of the skin, added to great prostration of strength, were the principal symptoms of gastro-intestinal inflammation. The breathing was unaffected. (*Five leeches to the epigastrium, mucilaginous drink, emollient cataplasm to the occipital region.*) The leech-bites bled freely. From the 7th to the 13th, the gastro-intestinal symptoms were treated by the warm bath, administered twice a day, and by emollient cataplasms and glysters. The little patient, mean time, was supported with gum-water, and milk and water mixed. On the 15th he was convalescent. During all this interval the affection of the scalp showed no improvement under the continued application of emollient cataplasms. The mother even assured me that the disease of the scalp had got worse since the inflammatory affection of the gastro-intestinal membrane supervened. I now removed the hair from the affected parts; the soothing poultices were continued; a blister was applied to the left arm, and twenty-five days afterwards the scalp was completely whole.

CASE LI.—*Repeated attacks of acute eczema rubrum at irregular intervals during a long succession of years.*—The following interesting case is given by Dr. Marcet, in the second volume of the *Medico-Chirurgical Transactions*:

I was called, he says, to attend a gentleman, about thirty years of age, rather of a spare habit, and pale complexion, for the first time, in March, 1808, on account of a complaint in the skin, which is apt to recur at irregular periods, and to which he has been subject, more or less, ever since the age of sixteen.

The attacks of the disease are generally preceded for a few hours by what the patient calls a twinging sensation at the pit of the stomach, but without nausea, fever, or even loss of appetite. He then begins to feel a sense of stiffness and heat in the various parts of the body; these parts, in a few hours, are observed to become red, and to swell rapidly to a considerable degree. The hands, the feet, the ears and the lips, are the parts which the disease principally attacks. But it also frequently appears in the face and eyes, and sometimes even in the hairy scalp. Indeed, in the severest attacks, there is no part of the body which can be said to be totally exempt from it. The extremities, however, especially the hands and feet, are by far the most conspicuous seats of the complaint.

When the parts are attentively examined on the second or third day of the disease, the cuticle appears to be raised in innumerable small vesicles, some of which are distinct, so as to give a roughness to the surface, though most of them are confluent, forming an uniform swelling, with a shining appearance. Soon, however, on the swelling abating, which commonly happens on the third or fourth day, the

cuticle begins to crack, and to rise in patches, discovering an inflamed surface, with numerous small superficial ulcerations, from which there oozes a fluid, having a strong disagreeable smell. On the extremities, and in the bends of the toes and finger-joints, pretty deep fissures or ulcerations are formed, which, however, heal readily, and in a day or two the cuticle falls off in large patches, sometimes as large as the hands, presenting an appearance which may be best compared to that of the trunk of the plane-tree when casting its bark. Sometimes the nails themselves are cast off, the new nail gradually pushing up the old one, which appears dead and withered. A few days after this, however, the new cuticle, which is at first red and inflamed, generally assumes its natural appearance, so that in the course of about a fortnight or three weeks from the beginning of the attack the complaint is commonly entirely removed. But at other times, and at the moment when the patient thinks himself convalescent, the new cuticle becomes hard and dry, and cracks again as in the first instance, producing a repetition of the symptoms just described.

When I saw this patient for the first time, (in March, 1808,) it was on the 4th or 5th day of the attack, which happened to be one of the most violent he had experienced for some years. The swelling was still conspicuous in many parts, and these were in both his hands, particularly in the palms, where the cuticle is the thickest, and between the fingers, deep cracks and ulcerations. He had, however, no fever, no thirst, no quickness of pulse, and he complained only of a sense of weight, heat, and stiffness in the affected parts. The corners of his mouth, the ears and the feet were this time but slightly affected.

Finding that amongst a variety of remedies and applications, which he had tried at various periods, with a view to relieve the immediate symptoms, he had never made use of poultices, I recommended a linseed-meal cataplasm, with twenty drops of the extractum litharg. acetat. to be applied to the hands. This produced a sensible diminution of the tension and swelling, and upon the whole, great relief was obtained by this application. But soon after the removal of the poultices, the heat and stiffness gradually returned, so as to require a repetition, and an almost uninterrupted use of the same application; and even during his convalescence (which took place in three or four days), and when the parts were fast returning to a natural state, he still found it expedient to have, occasionally, recourse to a poultice in order to remove uneasy sensations.

With regard to internal medicines, having no distinct precedent to assist me in the choice of any particular treatment, and seeing evidently, from my first visit, that the patient was gradually recovering, I contented myself with regulating the state of the stomach and bowels. But with a view to prevent the recurrence of similar paroxysms, I suggested that he should try a course of sarsaparilla, that he should make frequent use of neutral salts, and above all, that he should give a full trial to the warm bath, a remedy which, to my great surprise, had never been recommended to him before.

Upon inquiring into the general history of this uncommon disorder, I was informed that the attacks had of late years recurred two or three times in each year, and appeared to have no connection with particular seasons. Some of these attacks have been very slight, and they have sometimes been so partial as to be confined to one hand, or even to one finger. In these instances the patient thinks that the progress of the disease has been prevented by the use of nitre and aperient medicines.

This gentleman's general constitution appears to be delicate, though, excepting the complaint above described, he is not subject to any habitual ailment. In general he sweats easily and profusely upon the slightest exertion when in health; but, at the time of the attacks, he complains rather of a deficiency in that secretion. His diet is moderate, and he has in vain tried to trace his complaint to peculiarities of regimen.

Two years had elapsed, when, about the middle of last May, the same gentleman desired that I should see him again. I found him in a state perfectly analogous to that which I have just described, but with symptoms more severe than in the former instance, though still unattended with fever or other obvious constitutional affection. The desquamation of the cuticle all over his body was such, that on raising his bed-clothes the spot where he lay was found literally strewed

with scales, and I do not overrate the fact in saying, that a handful of these might easily have been collected. The hands, feet, lips, face and even the eyes, especially the outer corners of the eyelids, were the parts most severely affected. The cuticle of the heels in particular, and that of the soles of his feet, came off in patches as large as the palm of the hand. This attack had begun about twelve days before I saw him, with a sense of oppression in the præcordia, and it was immediately preceded by, and (he thinks) obviously connected with, his having been exposed to a severe shower of rain. After raging for a few days the complaint had in a great degree subsided, but had broken out again just before I saw him, with redoubled violence.

I had the satisfaction of finding, upon inquiry, that with the exception of some slight threatenings, this was the only attack which he had experienced for the last two years, and he ascribed his having been so much more free from his complaint, during that period, to the frequent use of the warm bath, and to the great attention he had paid to the state of his bowels. He had occasionally used cold sea-bathing with apparent benefit.

The same local treatment was adopted, as in the former instance, namely, the application of poultices to the hands and feet; and with regard to internal medicines, I ordered a saline antimonial mixture, which, by exciting a moisture on the surface, appeared to allay the tension and uneasiness. In the course of a week he was in a state of full convalescence.

Since writing the above, I accidentally met, a few days ago, (June, 1811,) the gentleman whose case I have related; he informed me that he had within these few weeks experienced another attack of the disease, perfectly similar to those I have described, though in a slighter degree.

March 1st, 1813. On inquiring into the state of my patient, of whom I had lost sight for the last twenty-one months, I found him just recovering from a severe attack of his complaint, with his cuticle partly renewed, partly falling off in large patches, of which he showed me a handful which he had just collected. He informed me that he had had eleven attacks of his disease since we had met last, that is about one every two months, some of which, however, had been very slight. The only additional particulars, I collected from him, were that he had found a brisk purgative more useful in mitigating the symptoms on their first appearance, than any other kind of remedy; and that, during the severer attacks, he had noticed a sensation of heat and irritation in his urethra, with some difficulty in passing his urine. His looks and general health are not materially impaired.

CASE LII.—*Congenital ophthalmia, aphthous inflammation of the mouth, roseola, strophulus, sordes of the scalp, slight eczema impetiginodes.* Madame A. B. was delivered, towards the end of March, 1826, of a female child, well formed, but with the conjunctivæ of both eyes slightly inflamed. This child was confided to a nurse of a delicate constitution, whose milk, though abundant, did not seem greatly to benefit the infant. Despite a variety of measures—soothing collyria, counter-irritants behind the ear and to the nape of the neck, and the warm bath persisted in for the space of a month, the affection of the eyes did not yield before the end of the seventh week. From the twelfth day after birth, the lips, the edges of the tongue and the inner surface of the cheeks were attacked with the pultaceous inflammation peculiar to new-born infants, and characterized as *aphthous*. The suckling was temporarily suspended, and the child fed on milk and water. Nearly at the same time the body became covered with a roseolous eruption so general that the nurse and the parents believed the infant to be attacked with measles. This affection disappeared completely in the course of the third day. The aphthous affection did not extend beyond the mouth; the evacuations of the infant, however, showed considerable disturbance of the primæ viæ. The suckling was recommenced with a strong nurse as soon as the child could take the breast without pain. The child seemed at first to suffer from griping in the bowels; and a number of large papulæ were evolved on the thighs and buttocks (*strophulus*); the child slept little, but took the breast freely, and the discharges from the bowels soon became natural. A slight discharge took place from behind one of the ears, which was rather encouraged, and at length a cluster of small yellow pustules appeared on the right cheek, and another of larger dimensions

on the parietal region of the same side. Both of these clusters of pustules speedily became covered over with a moist yellow incrustation which dried up in a few weeks afterwards,—that of the face falling off spontaneously and leaving a small red blotch upon the skin, that of the hairy scalp being removed by means of a softening poultice. By the same means a thick yellow, and, as it were, imbricated and very adherent scurf or sordes, which, since the period of birth, had formed a sort of covering to the scalp, was removed from its surface. The skin under this deposit, which extended some way over the naked part of the forehead, was quite healthy, and did not appear ever to have been inflamed. During the whole of the treatment the infant was put into the warm bath almost every day.

CASE LIII.—*Inveterate eczema impetiginodes; remarkable modifications in the appearance of the eruption (furfuraceous or squamous state of the face, hairy scalp, and palms of the hands).* P. B., a hackney coachman, fifty years of age, in the habitual enjoyment of good health, though he occasionally indulged in wine and brandy to excess. During the month of August, 1832, several small vesicular spots appeared on the right forearm. Feeling some uneasiness in the lumbar region, the patient applied a Burgundy pitch plaster to the part; the application was followed by an eruption that spread in the course of a few days to the thighs and legs, accompanied with severe itching, especially during the night, but which even in the day was occasionally so annoying as to oblige him to get down from his box that he might scratch himself more at his ease; this indulgence was accompanied and followed by the discharge of a quantity of reddish serum, which, concreting subsequently, formed scabs upon the diseased surfaces.

On his entry into the Hôpital de la Charité on the 11th of March, 1833, the legs were covered with thick yellowish or dirty gray-coloured incrustations, rough, laminated, and irregularly cracked in the course of moist and ragged-looking chaps of the skin. On the thighs, forearms, and lumbar region, the surface of the dermis under the incrustations was moist and excoriated, and sprinkled with points of a very vivid red, from which the discharge appeared to exude. The pruritus was not now much complained of; the patient's health was good, he slept quietly, and was free from any derangement of the principal functions (*twelve grains of the sulphuret of antimony; sulphureous baths, mucilaginous lemonade, the three quarters hospital allowance of food*). March 15th.—The sulphuret of antimony was carried the length of fifteen grains at each dose without producing uneasy feelings or moving the bowels. The sulphureous baths had modified the appearance of the eczema; the incrustations had partially disappeared; the exposed dermis was red and moist (*alum washes; alum ʒi, water lbs. ii.*). The alum washes occasioned severe scalding pains, and had to be discontinued after the second day. March 19th.—The patient was bled; the blood was not buffed, but very much cupped. The sulphuret of antimony in doses of thirty-six grains was continued to the 21st without inducing catharsis or any other appreciable effect on the system. Eighty grains of black hellebore produced no purgative effect, which speedily followed the exhibition of a few pills containing half a grain of the tartrate of antimony. These pills and the sulphureous baths were continued. One grain and a half of the tartrate of antimony, made up into three pills, and taken in the course of the twenty-four hours, kept the bowels constantly open up to the 14th of April, at which time the medicine began to cause vomiting, and the eczema, treated besides by compression, did not appear to be making any progress towards recovery. Its appearance varied exceedingly from day to day; the legs were alternately dry and scaly, or running and excoriated; the general health had suffered no change.

After being left quiet for a few days, the patient was put upon the solution of arseniate of soda in doses of thirty drops daily. About the 18th of April the appetite fell off remarkably, an occurrence which was followed by a notable exacerbation of the eczematous affection. On a sudden the pruritus became more troublesome, and the skin redder and covered with vesicles, from which an abundance of reddish serum was poured forth to concrete into scabs of considerable thickness, especially on the legs. The pruritus was now exceedingly severe, and was accompanied by a very painful sensation of heat in the diseased surfaces; the pulse became quicker, the sleep was disturbed, the appetite failed entirely. A copious bleeding gave an immediate check to these symptoms. The blood was buffed. Large cataplasms

were applied to the inflamed surfaces. Cold bathing was substituted for the sulphureous baths, and the patient was put upon whey. A few days of this regimen and treatment sufficed to allay the general excitement of the system and to lessen the inflamed state of the skin. Barley water, acidulated with nitric acid, was prescribed, and the arsenical solution recommenced. On the 6th of May the legs were free from scabs, and the skin had lost its redness; the excoriations were paler, but dotted with points of blood as if the skin had been slightly abraded by the action of a rasp. This improvement, however, did not continue long; renewed febrile symptoms were followed by a reappearance of the eruption. The patient was bled again, and again put upon the whey diet and the use of the cold bath. The blood was still buffy. The legs were gently anointed with lard, and covered with emollient cataplasms.

At this period the face was attacked with an eruption of a similar kind, followed by furfuraceous desquamation principally from the parts that were covered with hair. Small impetiginous scabs were also formed upon the eyebrows. The hairy scalp, especially its anterior part, was soon covered with a very abundant white and glistening desquamation, the scales of which clung to the hair. The skin, when rubbed and freed from this species of scurf, did not appear much inflamed.

On the palmar aspect of the hands, the desquamation had a different character. Large flaps of cuticle were detached from the skin, which appeared humid and red underneath them. The cold baths and whey diet were continued till towards the end of May, a period at which the eczema of the legs had a favourable aspect. The scabs were no longer reproduced, the discharge had almost entirely ceased, and the general state of the patient was satisfactory. June 11th.—The nitric acid sherbet was resumed, and the bathing continued. Lard was ordered to be rubbed upon the tender surfaces, and the disease appeared stationary; but on the 12th, the skin of the legs in several places again took on an inflammatory action, and became covered with impetiginous incrustations; the patient was bled for the third time, and after a few simple baths, improved once more. The patient left the hospital on the 24th of July, 1833, not completely well; the disease, however, had become supportable; the general health was good; the micaceous desquamation of the scalp still continued abundant, without itchiness or unpleasant sensations. (a)

(a) A good clinical lesson is conveyed in the following case, recited by Dr. Carswell (*ut supra*). "We now come to the consideration of the second case of eczema impetiginodes, which is one of considerable interest, even in a diagnostic point of view, owing to the unusually obscure and complicated appearances which it presented. I shall first read you the history of this case, taken from the case-book, before offering you the explanatory observations which it suggests.

"History of case.—John Smith, æt. 35, admitted December 4th, 1838, formerly a groom, but for the last three years has been employed as a gardener; he is of a sanguine temperament, tall and muscular, married, and of regular habits; parents are living, and generally healthy; his own health has always been remarkably good. Fourteen years ago (before his marriage) he contracted gonorrhœa, and got well in about a fortnight by the use of internal remedies. He declares he never had any venereal complaint since, nor, indeed, ever been in "harm's way." In the summer, six years ago, he had an eruption of small pimples all over his body, on glans penis and scrotum, as well as on other parts. These were attended with very little itching, and died away spontaneously towards winter; they have returned every summer about June. The eruption was supposed, by his medical attendant, to be syphilitic, and the patient was salivated three times within the twelve months, three years ago. At this time he states that he had a small swelling in the groin, which, however, soon subsided after leeching and rest. After the first salivation the eruption assumed a new form; the pimples broke and discharged a yellow fluid, which concreted into thick scabs. Similar pimples now began to appear on the scalp and face, being preceded by severe headaches. Each pimple broke, enlarged, joined with neighbouring ones, and formed large discharging surfaces, which afterwards gradually healed at the centre, on various parts of the head, trunk, and extremities. His throat became sore; there were large ulcers formed

CASE LIV.—*Eczema of the navel; rapid spontaneous cure followed by chronic gastritis; good effects of a blister and an issue in the original seat of the eruption.* F. J. M., forty-six years of age, was admitted

in it, and it continued in this state for two months. He became gradually worse and worse, and was, as stated, admitted the 4th December.

"Present symptoms.—His face is nearly covered with the eruption; the patches are irregular in size, but generally assume a circular form; some parts are erythematous, covered with a furfuraceous desquamation, and around the margins of these patches, which have healed in various degrees in the centre, the still discharging eruption forms scabs and crusts of a yellow colour, by the concreting of the matter furnished by the pustules. There are numerous patches on the head, behind the ears, &c. &c.; the margins of the patches are not raised, but the skin around is red and shining; the eruption heals in the centre of the patches, and the parts, once the seat of the disease, do not again become affected. The affected parts are hot, itch, and smart, and heat only makes them worse. There are several large patches on the back, and on the front of the chest, one on the left scapula, and one on the right breast, forming a complete ring. Another very large one is situated just below the knee, healed in the centre, the skin there being of the natural colour, and another patch under the left thigh, four inches in breadth. There are small red papulæ, containing fluid of a yellow colour, like impetiginous pustules, diffused over the body in various parts.

"The upper lip is much swollen and protruded; the eyelids are thickened; there are lippitudo and coryza; the sight is dim and impaired, and the eyeballs bloodshot.

The skin is, at times, very hot and dry; he is very much weakened by the disease; appetite is pretty good; thirst; sleep bad; very little perspiration; bowels regular; urine high-coloured, and rather increased in quantity; tongue clean and natural.

"The history of this case suggests two inquiries: first, the nature of the eruption considered in itself; and, secondly, its remote cause or origin. As to the eruption, it presented far from common appearances, both as regarded its general characters and the great extent of the surface which it affected; in some of its characters it bore a faint resemblance to psoriasis, particularly in the redness of the inflamed surfaces and the presence of the furfuraceous desquamations, or, rather, thin whitish, transparent, laminated scales, which covered a great part of these surfaces. It was, however, only in these respects that it had any resemblance to psoriasis, and that but a very imperfect one; for, in this disease, the squamæ are white and opaque, and are not only accumulated into thick rugous masses, in chronic cases, such as that of our patient, but the inflamed cutis is thickened, hardened, and fissured, which in this case was smooth and shining. Besides the somewhat scaly or squamous character of the affection, which gave to it a resemblance to psoriasis, there was also another circumstance calculated to lead astray, viz., the tendency of the large patches to heal in the centre; but this circumstance is observed in other and different cutaneous diseases, and particularly in that with which this patient was affected.

"Besides these negative characters of the disease, there was one of a positive nature, which at once served to distinguish it from psoriasis, viz., the *incrustations*, or *scabs*, which occupied principally the outer margin or circumference of several of the patches on different parts of the body. These were of a yellowish or yellowish-brown colour, obviously formed by the concreting of a viscid secretion, such, in fact, as is observed to occur in impetigo or eczema impetiginodes. No such kind of crust or viscid discharge occurs in psoriasis, although in some cases of psoriasis, inveterata, after an exacerbation of the inflammatory excitement, a slight discharge may take place; but even here the resemblance to impetigo is extremely remote in this as well as in many other circumstances.

"Could there have been any doubt as to the character of the disease, as indicated by the general appearances of the patches, and particularly by that of the scabs, this would have been removed by the presence of the impetiginous pustules on several parts of the body.<sup>1</sup>

<sup>1</sup> A model in wax of a part of the body affected with the disease was exhibited and described.

into the Hôpital de la Charité on the 3d of June, 1833. Five years prior to this date he had been troubled with an eruption over a space as broad as the palm of the hand around the navel, accompanied with smarting and pruritus, from which a quantity of red fluid was dis-

"This form of impetigo is, as I have already said, far from being common. It is observed in persons of a lymphatic or scrofulous constitution, and most frequently as a sequela of venereal infection, and possibly in those on whose constitutions mercury exercises an injurious influence. It is stated that this patient had a gonorrhœa fifteen years ago, which was removed in the course of about a fortnight after the use of internal remedies, probably no mercury having been employed. Nine years after he had, in summer, what appeared to have been a papular eruption over the whole body, including the glans penis, and which disappeared spontaneously towards the winter, and which had returned every summer since. This eruption was supposed, by the medical attendant of the patient, to be syphilitic, and three years ago he was salivated three times within the twelve months. Instead of this treatment having been of any service to the patient, the disease with which he was afflicted became worse after the first salivation. Instead of a papular there now appeared a pustular eruption, occupying first the head and face, and accompanied by severe headache. It was at this time, also, that the throat became affected, and was the seat of ulceration for about two months. From this period, also, the cutaneous disease increased in severity until it had arrived at that stage at which you saw it when he was admitted into this hospital.

"When I first saw this patient I did not attach much importance to the venereal origin of his disease, nor was this to me a matter of consequence, as the treatment employed was that which has been found to be, in most cases of this nature, by far the most efficacious.

"You have heard that he had fifteen years ago only a gonorrhœa, although our evidence on this point is by no means conclusive. However, were his statement correct, it would not be a solitary instance of syphilitic eruptions succeeding to gonorrhœa after intervals of many years. I have myself witnessed cases of this kind, in which the cutaneous affection itself, either of a scaly, vesicular, pustular, or tubercular character, bore sufficient evidence of its origin; and Biett, of the Hospital of St. Louis, of Paris, who has had the most extensive opportunities of investigating this subject, long since informed me that the occurrence of syphilitic eruptions after gonorrhœa was far from being uncommon.

"Numerous experiments, particularly those of M. Ricord, have, indeed, lately demonstrated that the primary affection of the mucous membrane is, in many cases of gonorrhœa, of the same nature as in chancre, the puriform discharge in these cases, when introduced into the cutis, being followed by the formation of a true venereal sore, or chancre, and its constitutional consequences. From a review of the history of this patient's case, therefore, you will no doubt be disposed to consider the vesiculo-pustular affection which he presented of syphilitic origin. The sore throat, combined with successive attacks of the cutaneous affection, would, by most physicians, be considered conclusive evidence in a case of this nature.

"The treatment in this case was in the highest degree successful; how far the cure will be permanent is yet a question. However, the further use of mercury in a case of this kind would have, I am certain, as it already had done, acted most injuriously. Indeed, I may say, that almost all the bad cases of syphilis which I have seen, more especially when the throat was extensively ulcerated, the nose destroyed, nodes of the bones, excruciating pains, &c., have occurred in persons who had undergone repeated courses of mercury, and without imputing this to the deleterious operation of the mercury alone, it is no less an important practical fact that such consequences too frequently follow the operation of this medicine in constitutions contaminated by syphilis.

"The following was the treatment adopted in this case:—

"Dec. 4. Venesection 3xii; *sol. of hyd. of potash*<sup>1</sup> 3ss thrice a day; middle diet.

"6. Blood bled and cupped; skin less hot.

<sup>1</sup> The solution of the hyd. of potass. employed in the hospital contains one drachm to the ounce of water.

charged; this in all likelihood was a cluster of eczematous vesicles. After continuing a month, the disease very quickly disappeared, without any kind of very active treatment having been employed for its cure. Previously to this attack the patient had never been affected with any symptoms of indigestion; but from this time he began to complain of a feeling of weight and a disordered state of the stomach and bowels. He now felt sick, and showed some inclination to vomit. Several days of rest, demulcent drinks, and leeches to the epigastric region subdued these unpleasant symptoms; but the digestive functions continued weak; the patient could not eat of every thing indifferently; he was only comfortable when taking milk and light broths; meat and wine were excluded from his regimen. The patient, after suffering in this way for fifteen months, got a little better, but the improvement did not continue long, and the former symptoms returned; he therefore sought admission into the Hôtel Dieu, where he was bled twice with leeches from the anus, and ordered to take the bath several times. He left the hospital in a fortnight very little relieved.

When M. entered La Charité, he looked pale and was considerably reduced. The tongue was white in the centre, and rather red at the tip; the epigastrium was painful. He complained of distaste to food, of flatulence, a painful sense of constriction across the stomach, especially after taking certain articles of food, amongst which fresh vegetables were particularly mentioned; he had also acid eructations, and a sour taste elung about the gums; he was occasionally sick and had a more copious secretion of saliva than proper. The stools were natural, the respiration was free, the pulse good; there was no heat of surface. The patient, however, was habitually dejected and melancholy. (*Demulcent gummy drink; beef tea, soup and milk for diet; and with a view to restore the eruption of the navel, the recession or suppression of which seemed to have preceded all the gastric symptoms since endured by the patient, a blister was applied over the umbilicus.*) June 9th.—The patient, whose sensations appear to be very acute, complained of his inability to bear the pain of the blister; one-half of the blistered surface was therefore allowed to heal up; the other was kept open, and so long as the artificial inflammation thus excited was maintained, the stomach felt less oppressed and the digestive powers appeared stronger. The patient, however, made new complaints of the blister, and it was healed up on the 16th, but replaced on the 18th by a small issue established above the navel. After the 25th the improvement was remarkable. The tongue became less loaded, and the countenance wore a better aspect. Milk, and a very small quantity of solid food, now composed the diet of the patient. On the 5th of July he requested to be discharged. The digestive functions were then greatly improved; the appetite was better, the patient ate and digested without difficulty the quarter hos-

"R. *Creasote*, one drop;

*Water* 3vj; a lotion for the affected part.

"8. Lotion caused some smarting, and was decreased in strength; two ounces additional of water. Increase solution to two scruples.

"11. Heat and itching less; eruption paler. *Sol. of hyd. of potass.* 3i.

"15. Improving rapidly. *Sol. of hyd. of potass.* 3½ scruples.

"18. Much less redness, heat, and smarting; lotion diminished in strength from its causing too much tingling. *Sol. of hyd. of potass.* four scruples.

"22. Eruption still less red and tingling; patient feels much easier, but had an attack of headache and sickness, from having taken 3ss of the solution, by mistake, more than was ordered.

"25. Venesection 3vj; *sol. of hyd. of potass.* 3iss.

"From this period up to the 10th of January, the general health of the patient and the cutaneous affection gradually and steadily improved.

"The use of the creasote lotion was continued, with some variation in its strength, and the solution of the hydriodate of potash gradually increased to ʒv. A few days after the patient was allowed a more generous diet. On the 22d he was nearly well, desirous of returning home; and on the 24th was discharged cured, the only remains of the cutaneous disease consisting in a reddish discoloration of the parts of the skin which were affected by the eruption."

pital allowance, and could even take a little wine without inconvenience. He was discharged with a recommendation to keep the issue open. (a.)

(a) The following cases related by Mr. Erichsen (*Med. Gaz.*, May, 1843), will illustrate the value of the arsenical treatment.

"The only disease," says Mr. E., "amongst the vesiculæ that can ever necessitate the employment of arsenic is *chronic eczema*. This is more particularly the case when this affection, as has already been stated, has assumed a furfuraceous or scaly condition, closely resembling some forms of psoriasis, or pityriasis, and indeed in some instances, as Biett has shown, actually passing into these diseases; the scales becoming dry, laminated, and of a whitish, grayish, or yellowish-gray colour; the subjacent skin being red, thickened, cracked, and inflamed; the vesicular element, however, reappearing in the progress towards a cure. However obstinate this form of the disease may usually be, it becomes particularly intractable when affecting certain regions of the body, as the scrotum, labia, and inside of the thighs, and will, when of old standing in these situations, seldom yield to any remedy but arsenic. The following is a case in point:—

"Mr. W. B., æt. 49, of relaxed debilitated habit of body, applied to me, in October last, for a disease of the scrotum, thighs, and breast, under which he had been labouring between four and five years. He ascribed his complaint to his having drunk some porter when overheated, soon after which act of imprudence he experienced considerable irritation about the scrotum and thighs, on which parts a vesicular eruption made its appearance: this was followed by a scaly condition of the parts, and the affection, after a time, spread to other parts of the body, as the arms and chest. He has been subjected to a variety of treatment, and has been salivated twice, but without deriving any benefit. When he applied to me, the scrotum and inner aspect of the thighs were covered by a number of thin, flimsy, yellowish-gray scabs, from under and between which an occasional exudation of a serous fluid took place; the subjacent skin was red, inflamed, and fissured, and there were several patches of a similar character upon the chest, occupying a space of about the size of the hand, as well as one on the right arm. The itching and tingling in the affected parts were severe, so much so that it was with difficulty that he could keep his hands from tearing them. When I first saw him his mouth was sore from the effects of some mercurial that had been ordered by the physician who last attended him, and by whom he was sent to me. He was, therefore, in the first instance, merely directed to take some aperient medicines, and to make use of soothing applications to the affected parts. On the 4th November he was put upon a course of Fowler's solution, beginning with two and a half minims twice a day, and increasing the quantity up to six minims three times a day; this was continued, with two intermissions on account of constitutional disturbance, up to nearly the end of December, when the disease was entirely cured. The external applications that were had recourse to were, in the first instance, the ointment of the white precipitate, which was, as the disease became more passive in its characters, changed for that of the biniodide of mercury, diluted with four parts of spermaceti ointment.

"Useful as the solution of the arsenite of potassa unquestionably is in cases similar to the preceding one, it is equally serviceable in dry chronic eczema affecting other parts of the body, as the following instance will illustrate.

"Eliza Penny, æt. 16, of a lymphatico-bilious temperament, came under my care on the 17th November, 1842, for a disease of both arms under which she had laboured from the very earliest infancy (from the age of three months). The affection in question was clearly eczematous. The diseased integument appeared thicker and rougher than natural, was covered with flimsy exfoliations of the epidermis, was exceedingly irritable, itching and tingling to an intense degree when the patient got warm, and was much fissured about the bends of the elbows and wrists. There was every now and then an exacerbation of the disease with a distinct eruption of vesicles. The patient complained much of languor and lassitude, was pale, or rather sallow in complexion, and menstruated somewhat irregularly. She was ordered the diluted mineral acids internally, with the oxide of zinc

ointment to the affected parts, and the pil. aloes cum myrrhâ, to regulate the bowels and menstrual functions. Under this plan of treatment the general health improved somewhat, and the irritability of the affected skin was subdued. She was then, on the 2d January, ordered to begin the solution of the arsenite of potassa in two-minim doses; these were gradually increased to five, and subsequently to seven and a half minims, three times a day: this she continued for a space of two months and a half, until the middle of March, without being obliged to intermit its use for a single day, at the expiration of which period the arms had assumed a healthy appearance, the skin being smooth, soft, and supple, perfectly free from scales, and without any harshness; it was, however, owing probably to the very long time it had been diseased, of a yellowish or tawny colour, darker than that of the rest of the body. The only external applications used were, in the earlier stages, the ointment of the oxide of zinc, with occasional fomentations during the exacerbations of the disease. These were followed by the ointment of the white precipitate, and subsequently by a lotion of the sulphuret of potassium, in the proportions of a drachm of the salt to a pint of water. The local disease was not only cured, but the general health very decidedly improved by the administration of the arsenic; the patient having gained flesh and strength, acquired a good colour, and declared herself to be in better health than she had ever enjoyed."

In support of a different mode of practice, and as a lesson in diagnosis, I introduce the following "*Aggravated case of eczema rubrum on the genital organs, mistaken for syphilis*. By W. Acton, Esq., Surgeon to the Islington Dispensary. (Read before the Westminster Medical Society.)" A child, nine weeks old, was brought to me by its mother, in great alarm, in consequence of having been told by a medical man that the complaint was venereal.

"The child was a fine stout boy, but very fretful. The eyebrows presented distinct vesicles of eczema. The inside of the mouth and lips free from disease, but just at their margins, and extending for the space of an inch and a half, completely encircling the mouth, the skin presented a dusky hue, and appeared covered with a thin, shining, dry pellicle, like a recent blistered surface, interrupted with cracks and crevices, without exudation, except beneath the chin, where the capstrapping had irritated the surface; and here a serous-looking fluid exuded, and excoriated the surrounding parts. Beyond this, distinct and separate clusters of vesicles could be seen, presenting a dusky hue. On the arms and chest a few small patches of these vesicles were apparent. The disease, however, seemed to have settled principally on the lower part of the abdomen, scrotum, thighs, and nates. The entire surface of these parts presented a shining, but dark or dusky-red surface, as if covered with a thin pellicle, similar in appearance to that found on a healing blistered surface. The temperature of the surface was much above that of the surrounding parts; no vesicles could be detected; this unhealthy-looking skin was creased and plaited, with a disposition to crack; in many places large thin flakes could be detached; every movement the child made appeared to cause great pain.

"The mother states that her other two children are, and have been, quite healthy; her husband has never complained of illness; she has suckled her own child, which has never been out of her sight; has never nursed any other woman's infant. The child enjoyed good health until three weeks old; at this period it was seized with thrush; the throat became affected, and soon after an eruption appeared around the arms, which has gradually spread over the parts now affected. For some weeks the child was under the care of her usual medical attendant, and treated with powders and ointment; the mother, finding the complaint getting worse, consulted another medical man, who, after looking at her boy, told her not to be offended, but her child had the venereal disease, and mercury was necessary for its cure. He prescribed a gray powder twice a day. The terror of the mother was, as may be supposed, great, when made acquainted with her child's complaint; for herself she could reply, and as to her husband's conduct she never had entertained the least suspicion. The medical man was no less positive, and further enjoined her not to suckle the

body becomes of as bright a red as in the first variety. In men, the eruption usually begins on the scrotum and insides of the thighs: occasionally, however, it makes its appearance on the backs of the hands and arms, and still more frequently, on the back and belly simultaneously. Dr. Duncan speaks of a case in which the disease began in the face, which is generally one of the parts last affected. The vesicles are more apparent in *hydrargyria febrilis* than in *hydrargyria mitis*, especially at the beginning of the eruption; at a later period, the contact and friction of the clothes are apt to destroy them. Very small and transparent at first, and surrounded by a red circle, the vesicles of *hydrargyria febrilis*, before long, acquire the size of pins' heads, and become opaque and purulent. When the eruption begins to disappear, it bears a strong resemblance to the efflorescence of scarlatina anginosa on the decline; *hydrargyria*, however, always preserves a deeper shade of colour.

The heat of the skin occasionally reaches to the thirty-eighth degree of the centigrade scale; in no disease perhaps is it so incessant and so distressing. When the eruption extends in large patches, a thick and very offensive discharge takes place from the parts where two surfaces of the skin come in contact, such as the axillæ, the groins, the upper and inner parts of the thighs, &c. The *desquamation* rarely begins at a later period than the fourth day after the appearance of the eruption. The slighter the disease has been, the sooner does the exfoliation of the epidermis commence; it is thrown off in larger pieces in the febrile than in the mild variety of the disease. The desquamation is generally preceded by some soreness of the throat, which appears to be the cause of the detachment of the epithelium of the velum palati and pharynx.

A second exfoliation of the cuticle occasionally happens, and the skin then appears as red as before the first took place; it is only after repeated falls and renewals of the epidermis that the skin in many cases at length regains its natural colour; when this is once removed, the cuticle is no longer detached. This peculiarity has been observed especially in those cases in which the use of mercury was continued after the appearance of the disease.

Headache, nausea, a foul white state of the tongue, constipation, a sense of oppression, violent cough and difficulty of breathing,—such are the general symptoms most usually observed on the breaking out of the eruption; the pulse beats from a hundred to a hundred and thirty times in a minute, the thirst is unquenchable, and the patients call incessantly for acid drinks. At the epoch of the eruption the urine is scanty and high-coloured; it becomes more copious, and deposits a furfuraceous sediment towards the decline of the disease; there is generally either constipation or diarrhœa, and these may alternate with the eruption.

In one case, observed by Alley, the stomach continued irritable and threw off fluids of every description taken into it during the whole course of the disease.

The fever declines when the period of desquamation arrives, and usually terminates towards the eleventh day.

3. The most common cause of *hydrargyria maligna* is the continued use of mercury, or its absorption by the lungs, after the appearance of the first vesicles. A patient labouring under *hydrargyria mitis*, was subsequently attacked with the malignant form of the disease from having remained in the ward of an hospital of Dublin where mercury was administered to others. Many similar facts demonstrate that mercury may in this way act upon or be absorbed into the system.

However this may be, *hydrargyria maligna* is characterized by the following symptoms: the heat of the skin often rises as high as the 42d degree of the centigrade scale; the throat and tonsils are extremely painful; the eruption is of a deep or purple red colour; the face is so much swelled that the features are obscured; the eyelids, completely closed, are lost in the general tumefaction; and when the vesicles break and discharge, the eyes become excessively painful. The skin, swollen and very tender, is covered with vesicles of greater size than in the other varieties of the disease, which pour out a large quantity of acrid fluid. The vesicles are so closely crowded together that the whole epidermis is detached as in variola complicated with measles. The odour of the discharge is characteristic, and by one writer (Spens) has been compared to that exhaled by putrid fish; it is so disagreeable that it makes the patient himself as well as the attendants sick. In

one case related by Alley, in which the cuticle was detached from the back, a discharge of blood instead of serum took place.

The epidermis is thrown off at a much later period in this than in either of the two former varieties, and scarcely happens before the fortieth day from the date of the eruption. The cuticle occasionally falls entire from the hand like a glove. Thick yellow scabs follow the detachment of the epidermis, which peel off in layers; a fresh incrustation succeeds a fresh flow of serum, and each new desquamation discovers a surface less and less red; at length, no further discharge takes place, and a natural healthy cuticle is reproduced. The skin may, nevertheless, continue rough and scaly. The nails of the feet and hands are occasionally detached at the same time, or a little later than the epidermis. In a case, related by Pearson, not only were the nails lost, but such as replaced them were imperfect and deformed, like those of persons who have laboured under eczematous onychia.

Whilst the exfoliation of the cuticle is taking place in one district, a serous or purulent discharge is often going on in another; and when the disease has disappeared from almost the whole surface of the body, a single part may remain painful and inflamed; such was the case in a patient spoken of by Carmichael; the eruption vanished everywhere except from the arms and hands, which remained red and painful, and continued to discharge for three weeks after all the rest of the surface was whole; such was also the case with a young man, treated by Spens, in whom the disease, after having invaded the lower part of the abdomen, the genital organs, the upper and inner parts of the thighs and the hairy scalp, continued long on the latter part, after having rapidly got well on all the others.

As after-consequences of *hydrargyria maligna*, we often observe painful inflammatory affections of the lymphatic glands, large abscesses of the axillæ, and boils on other parts of the body. The skin may also become greatly altered in its external layers. One patient, on his recovery from an attack of *hydrargyria maligna*, was found to have lost all traces of the small-pox, with which he had been marked before. Pearson has seen the hair of the head, beard, axillæ, pubes, and, in great part, of the eyebrows fall off; the eyelashes are more rarely lost, even when the eyelids have been inflamed.

The fever of this form of *hydrargyria*, usually attended with great depression, difficulty of breathing, troublesome cough, fixed pain in the chest, and occasionally with spitting of blood and a sense of suffocation, is generally high in the same proportion as the external inflammation is violent. The pulse is hard and full as it is in pneumonia; the throat is very sore; the voice occasionally hoarse; the tongue, at first white, soon becomes yellow and brown at the base; in one case, however, mentioned by Spens, it continued moist and clean during the whole course of the disease.

Alley only met with a single case in which the appetite was undiminished, but Mullins speaks of an individual attacked with the disease in its severest form, who was hardly satisfied with double the usual hospital allowance of food.

During the whole continuance of the disease patients complain greatly of weakness and depression; their sleep, too, is interrupted, and opium only brings short intervals of forgetfulness. The pain endured is occasionally extreme; words convey no expression of its amount. One of Spens' patients, speaking of what he suffered, said he felt "as if his flesh were torn from his bones!" In the severest cases, a copious and fetid diarrhœa, delirium and coma precede the fatal termination.

The anorexia is commonly as strongly marked in *hydrargyria maligna* as in ordinary febrile affections. One of Alley's patients suffered from convulsions, another passed his urine and feces involuntarily.

Chilly and painful sensations of the skin usually denote an increase or a relapse of the disease, and each renewal is accompanied with the same kind of inflammatory fever as that which ushers in the first attack.

Gangrenous sores, fistula in ano, phthisis pulmonalis, marasmus, &c., have been observed to follow in the train of *hydrargyria maligna*.

These are the three principal forms or varieties of *hydrargyria* which have been described; I ought to say, however, that the disease has been seen to begin in a manner little severe in appearance,

and at a later period exhibit the most alarming symptoms; I have also to state that relapses are more serious and continue longer than first attacks; that the febrile symptoms do not always correspond with the intensity of the outward inflammation; and lastly, that the eruption, though partial, may be followed by painful and repeated desquamations of the cuticle.

*Causes.*—I have seen, and have myself treated a considerable number of patients in whom the exhibition of calomel and the inunction of mercurial ointment were followed by profuse salivation. I have also had a great many water-gilders under my care affected with mercurial trembling or shaking of the limbs; but in all the twenty years I have been engaged in the study of my profession, I have only seen three cases of hydrargyria. How is it, then, that this disease is so rare in France? The disease is incontestably produced by the exhibition of mercury, and the simple discontinuance of this substance often checks its progress, whilst the continued use of the medicine certainly aggravates the symptoms, as its recurrence is induced by too speedy a resumption of the remedy after convalescence from an attack. It would appear, therefore, that some predisposition in the skin or general constitution, or some combination of circumstances, little understood, was required for the production of this disease. We know that certain individuals are extremely unsusceptible of the action of mercury in every shape, whilst others cannot make use of even the smallest quantity of any of its preparations without experiencing its peculiar effects.

Some of those who have suffered from hydrargyria have only had one attack of the disease, although they have undergone several courses of mercury; others after having been affected with the eruption at the beginning of a course, have been enabled to renew it after a time without further inconvenience; in others, in fine, the eruption has only broken out after salivation and the usual signs of the mercurial action have been induced, or in consequence of exposure to cold or some other accidental cause. (a) No age appears to give immunity from the disease, although Pearson remarks, that he never met with a case in a patient above fifty.

The disease is occasionally benign in its character, although a large

(a) Mr. Colles (*Practical Observations on the Venereal Disease, and on the use of Mercury*), tells us that all danger of hydrargyria is removed after ptyalism is fully established.

“What is most worthy of remark is this, that we never find this eruption to make its appearance while the system is under the influence of ptyalism. So that, after we have ptyalism fully established, we may dismiss all our fears on account of this rash. But let us not be lulled into a false security merely because this symptom may not appear in the early part of a mercurial course: for in some instances it does not appear until the mercury has been used for a considerable time.

“I recollect the case of a young woman affected with an induration of one of her breasts, for which I had directed small doses of pil. hydr. combined with extr. conii. No sensible mercurial effect having been produced at the end of three weeks, I increased the dose of the pills; the result was very speedily a slight degree of ptyalism, and with it very full eruption of mercurial erythema, which proved tedious, obstinate, and alarming.

“In this case it is obvious that the eruption attended that slight febrile excitement of the system which mercury so generally occasions when it is just about to act on the constitution. During the first three weeks of its use, the mercury had not produced any sensible effect, and therefore had not excited this eruption. We may in fact declare, that at whatever period of a course of mercury the mercurial fever is first suddenly excited, there is danger of the erythema. Hence it should be a rule with those who are conducting a course of mercury, to watch carefully the earliest effects of each increase in the doses of the medicine, and to question the patient minutely, that he may get the earliest notice of the presence of this affection. When once the first burst of mercurial fever is over, and ptyalism has been fairly established, then the surgeon may carry on the mercurial process to any length of time necessary, (provided he do not allow the action of the mercury to subside,) and yet be under no apprehension of an attack of this rash.”

quantity of mercury has been used previously to its invasion; in other instances, it is malignant and severe after the employment of a comparatively very small portion of the metal, and even before what is called the mercurialization of the system can be supposed to have taken place. An adult became affected with hydrargyria after having taken two grains of the protochloride of mercury (calomel) for two days. (Alley, case IV.) Dr. Dunean saw the same thing happen to a girl nine years of age. Three grains of calomel, administered to a child seven years old as a purgative, have produced the mercurial eruption. (Alley, case III.) The father of this child had been attacked with hydrargyria *maligna* twenty years before, whilst pursuing a mercurial course on account of venereal symptoms. Two sisters became affected with the disease in the Dublin Lock Hospital, after having rubbed in three drachms of camphorated mercurial ointment. (Alley, cases I and II.) One of the severest cases seen by Alley was produced by a *single blue pill*. Lastly, Pearson informs us, that he has seen the disease brought on by the simple contact of the mercurial ointment, and even by that of a few grains of red precipitate.

At Dublin, mercurial frictions appeared more frequently to induce the disease than any preparation of mercury administered internally. Alley supposes that the quantity of camphor which enters into the mercurial ointment (scr. ii to i oz.) used at the Dublin Lock Hospital, is not perhaps without influence in the frequent occurrence of the disease in that establishment.

The symptoms of bronchial affection observed during the course of the disease, induced Dr. Gregory to suppose that cold was one of the potential causes of hydrargyria. A correspondent of Spens', who writes from Madras, also informs him, that the complaint is very frequent among the natives there, who can with difficulty be persuaded to clothe themselves properly during a mercurial course. On the other hand, however, the same catarrhal symptoms have been observed to accompany the disease, under the influence of a very mild temperature.

Men appear to me more subject to this affection than women:

	Hydrarg. mitis.	Hydrarg. febrilis.	Hydrarg. maligna.	Total.	Died.	Cured.
Men.	6	12	10	28	6	22
Women.	4	7	4	15	2	13
Total.	10	19	14	43	8	35

The whole of the cases in the preceding table were seen by Alley within ten years: in three instances only did he meet with the disease in children, in none of which was mercury administered for a venereal cause: in the greater number of adults, the mineral was employed in the treatment of primary or secondary syphilitic symptoms.

360. *Diagnosis.*—To distinguish hydrargyria from other diseases, it is enough to remember that this vesicular affection is induced by mercury; that the eruption and the fever are isochronous, that the inflamed skin in different places secretes a fluid, the odour of which is characteristic; that the desquamation, preceded by pain of the throat and tonsils, occurs from the fourth to the eighth day, &c. It is true that eczema *rubrum* has all the external characters of hydrargyria, the same redness of the skin, and the same form of vesicles. But eczema, unlike hydrargyria, acknowledges no special cause, neither is it, but very rarely, so general; neither is it attended with inflammation of the mouth, sore throat, or salivation. Hydrargyria is essentially an acute disease; eczema *rubrum* is almost uniformly chronic in its character. Hydrargyria is still more easily distinguished from the discreet pustular affection which is often produced by the friction of rancid mercurial ointment upon parts covered with hair; and it will not readily be confounded with any other form of artificial inflammation of the skin. It is well known that mussels, bitter almonds, mushrooms, lobsters, pickled salmon, &c., may cause eruptions which bear some resemblance to scarlatina, erythema, or hydrargyria. Peculiar eruptions have also been observed among the natives of different coasts, who live much on particular species of fish. Alley saw a vesicular eruption of the colour of a boiled lobster, caused by eating a spoiled mackerel. General eruptions have also been seen to follow the administration of camphor and several other medicines. A

knowledge of these facts, and of the circumstances under which hydrargyria is developed, makes mistake all but impossible. (a)

361. *Prognosis*.—In two cases of gonorrhœa, Alley tells us that the discharge ceased on the appearance of hydrargyria, and did not recur after the cure of this eruption. This suspension or disappearance of symptoms is not confined to those of a syphilitic nature only. One patient who commenced rubbing in mercurial ointment on account of a hepatic affection, was soon after attacked with hydrargyria, and the disease of the liver disappeared; another who had taken a solution of the bi-chloride of mercury, (corrosive sublimate,) under the care of a quack, for a similar affection, suffered in the same way, with the same fortunate result. These cures, however, which are mentioned by Alley, were only observed to follow when the mercurial affection appeared under the febrile or the malignant form. Hydrargyria *mitis* produces little or no abatement in the symptoms of syphilis, whether the affection be local or constitutional, nor in those of any other disease. It has also been observed, that when primary syphilitic symptoms appear to be removed on the occurrence of hydrargyria, they almost always reappear after the diminution of the fever which accompanies the mercurial eruption. This is a circumstance which has been remarked by more than one practitioner.

Hydrargyria, being a modification of the constitution other than that generally effected by the action of mercury, Alley, Crampton,

(a) Mr. Colles (*op. cit.*) thinks it necessary to establish a diagnosis between hydrargyria (*erythema mercuriale*) and another more partial eruption also induced by mercury.

"We should carefully distinguish between *erythema mercuriale* and another but more partial eruption arising from the use of mercury. They both come on under similar circumstances; both seem to be excited by the first impression of mercury on the general system. Our attention is attracted to this latter eruption by our patient informing us that he fears he has got the itch—that he could scarcely get a wink of sleep for one or more nights preceding. He then exhibits on his hands and wrists an eruption beginning with small but very distinct red papulæ, some of which, in a more advanced stage, have vesicles on their apices: they chiefly occupy the anterior surface of each wrist, and of the forearm half way up to the elbow; the backs of the hands and fingers are also thickly beset with them. On first view, this eruption closely resembles a form of itch, in which the vesicles are small; but, on more careful examination, you discover that the clefts between the fingers are altogether free from the former, while they are known to be the principal seat of the latter. This eruption is accompanied by a slight degree of fever, and generally by marks of commencing pytalism.

"I cannot say what changes or effects on this eruption would be produced by persevering in the use of mercury, because all the patients in whom I witnessed this symptom were also affected with a smart degree of fever, and complained so bitterly of the itching and of the restlessness caused by it, that I felt afraid to go on with the mercury until the irritation of this eruption had subsided. A few days' use of the antiphlogistic regimen, and abstinence from mercury at the same time, were sufficient for the desquamation of the pustules, and the removal of this rare effect of the mineral.

"I need hardly observe that this eruption differs from the mercurial erythema, by the early appearance of the vesicles—by the eruption being much more distinct, and less thickly set in the skin—by the parts of the body which it affects, and, we may add, by its not extending to the other parts of the body, and not seizing on the angles of flexion in the limbs, where two skins occasionally lie in contact with each other. I suspect this effect of mercury is observed only in cases where the patient is using mercurial frictions. Here, as well as in mercurial erythema, we observe a decided improvement in the primary symptoms uniformly to occur.

"Having for some time noticed this eruption only among the soldiers under my care in the hospital, I at first suspected that it was produced in a great degree by the oatmeal diet, to which they are so much accustomed; but subsequent observation has removed this error, and convinced me that it is attributable solely to the use of mercury. Of course the use of mercury must be resumed as soon as the itching has ceased, and the eruption begins to desquamate."

34

and Willan, conceive that the appearance of this eruption ought to have no influence on the duration of the treatment requisite in venereal cases. Several practitioners have, however, been of a contrary opinion, and have stated, that only a very small quantity of mercury became subsequently necessary for the cure of these affections.

Messrs. Garnett and Wilmot, surgeons of the Lock Hospital, never saw hydrargyria so violent as to cause serious fears for the patient's safety, a circumstance which they attribute to their constant rule of immediately suspending the mercury on the first appearance of the disease. Crampton never saw the disease prove fatal, except in a few cases, in which the patients, the eruption being held venereal, persevered in the use of mercury. According to him, the fever which accompanies the eruption, whatever its degree of violence, is never important; the danger of the secondary fever which is lighted up when the skin becomes affected with a purulent discharge, is in proportion to the extent of the denuded and secreting surface. The fever occasionally then loses its inflammatory type, and assumes the hectic character. The patients are seized with shivering fits and tremors of the limbs; they complain of extreme weakness, and show a greater degree of emaciation than can be laid to the score of the discharge. (a)

362. *Treatment*.—To effect the cure of hydrargyria *mitis*, nothing more is necessary than to suspend the use of mercury, to abstract the patient from the influence of a mercurial atmosphere, if he be exposed to one, and to prescribe diluents, a gentle aperient or two, and an occasional warm bath. Pearson was occasionally induced, by considerations unconnected with the best treatment of the affection, to order the mercury to be continued in despite of its appearance. When the disease is on the decline, the use of mercury may occasionally be resumed with advantage, to combat the syphilitic affection for which it was first prescribed: in Davidson's case, related by Dr. Spens, the medicine was given under these circumstances, and the cure of the eruption advanced with not the less rapidity on this account. Another patient who had an ulcerated bubo in the left groin, was attacked with hydrargyria: when the eruption began to give way, a blue pill was prescribed night and morning, and the bubo got well without the affection of the skin being aggravated.

In the *febrile* and *malignant* species of hydrargyria, nothing could warrant the continuance of mercury in any form. By abandoning its use at once, an attack of hydrargyria, which commenced with violence, has occasionally been disarmed of its formidable aspect; the neglect of this simple precaution, on the contrary, has in some unfortunate cases, rendered the most energetic subsequent treatment unavailing in warding off a fatal termination. Like salivation, hydrargyria once established, seems to have a kind of necessary course to run. Pearson and Alley, therefore, agree in believing that though the more painful symptoms of the affection may be soothed by appropriate remedies, yet that no treatment is adequate to check it in its progress.

In hydrargyria *febrilis* and hydrargyria *maligna*, cold ablution or sponging, allays the distressing sense of heat which attends the eruption. The tepid or cold bath is also extremely useful when the condition of the patient does not prevent its repetition at short intervals. One of Spens' patients found the warm bath extremely soothing; but it could not be repeated on account of the syncope it produced. Next to frequent immersion in cold or tepid water, purgatives are the best means of diminishing the excessive heat of skin which accompanies hydrargyria. Crampton was in the habit of ordering powder of jalap combined with some of the neutral salts; Spens' medicine was the electuary of senna with an equal quantity of sublimed sulphur; Alley believed the super-tartrate of potash a preferable purgative to either of these formulæ. Mercurial purgatives ought, of course, to be avoided.

When the pulse is full and frequent, blood ought to be taken away, especially when any bronchial affection complicates the mercurial diseases. Alley saw one patient lost through want of recourse to this measure. The mercurial pulmonary affection, however, will also frequently be found to yield to purgatives.

Blisters are occasionally indicated, and may prove useful; but

(a) Mr. Colles, in his large experience, only saw one case in which the fever lasted more than eight days.

some practitioners are afraid to resort to these upon surfaces so highly inflamed and covered with vesicles, as they are in hydrargyria.

Those cases in which the tartrate of antimony might prove a useful medicine, have not been well determined.

The thirst is best allayed by acidulous drinks.

Pearson recommends opium to procure sleep, lessen pain, and check the diarrhoea, which almost always occurs during the secondary fever. Opiates and Peruvian bark are occasionally exhibited along with some generous wine during the continuance of the purulent discharge in hydrargyria *maligna*.

To prevent the absorption of the discharge into the system, and to promote the formation of a new epidermis, some drying powder, such as finely powdered charcoal, and liniments containing lime-water, have been advised. Alley was no advocate for any form of topical application containing lead.

To recapitulate, cold lotions, tepid baths, bland diet, purgatives and opium are the usual remedies in hydrargyria; blood-letting and tonics are only required in the severer, and happily the rarer, cases of the disease. (a)

#### *Historical Notices and particular Cases of the Disease.*

363. Among the writings of Th. Bonetus,<sup>1</sup> and in those of B. Bell,<sup>2</sup> several passages occur that evidently refer to hydrargyria. Jussieu<sup>3</sup> mentions an eruption of pustules affecting the skin of the workmen employed in the quicksilver mines of Spain. Cullerier,<sup>4</sup> and M. Lagneau<sup>5</sup> seem to refer to hydrargyria under the title of *erysipelas caused by mercury*.

The medical practitioners of Dublin having had the most frequent opportunities of studying this disease, their writings, and especially the works of Alley, have supplied the greater part of the information here laid before the reader. Dr. Burrowes, Physician to the House of Industry, Dublin, the late Dr. Gregory, Professor of the Practice of Medicine in the University of Edinburgh, and Mr. Dease, Professor of Surgery to the Royal College of Surgeons in Ireland, were the first who recognized mercury as the cause of this disease, to which Dr. Stokes, of Dublin, called the attention of his pupils during his course of 1798. Dr. Alley<sup>6</sup> was the first who published a good special treatise on the affection. Three months after the appearance of this publication, Dr. Moriarty<sup>7</sup> gave the results of his own and of Dr. Whitley Stokes' experience in the disease, which he describes under the title of *Mercurial Lepra*. Dr. Thomas Spens, in the Edinburgh

(a) "With respect to local treatment, I believe," says Mr. Colles, "that dusting the excoriated parts with any of the mild drying powders, will be found to afford as much relief as any other application. Sometimes the application of cloths, wetted with the black wash, has procured relief, and has appeared to promote the formation of cuticle. In a very severe case it will be necessary to have the sheets in which the patient is laid prepared so as to prevent them from sticking to the skin; I think that this is very effectually done by a mild ointment of rather a stiff consistence. The common one, made of equal parts of suet and beeswax, spread as thin as it can be spread by holding the spatula on its edge, will answer extremely well. I do not pretend to say that some other composition may not be discovered which will better promote the healing of the excoriated surface, but whatever it be, I should recommend it to be made of a firm consistence, for the softer ointments, by the heat of the body, are found to run quickly through the sheets, and consequently to leave the surface which is applied to the body nearly dry.

"I may next remark, that an obvious amendment takes place in the symptoms of the venereal disease, on the first appearance of this eruption, and that in a degree more striking than that which attends so slight a degree of pyalism."

Medical and Surgical Journal, No. 1, 1805, and No. 7, 1806, under the name of *Mercurial Erythema*, gave three cases of the disease which occurred in the Royal Infirmary of that town. Dr. Mullins<sup>8</sup> published a translation of his inaugural dissertation defended at Edinburgh in 1805, in the same periodical. Dr. John Pearson<sup>9</sup> subsequently gave an exact description of the disease under the name of *eczema mercuriale*, or eruption produced by the use of mercury. For additional information on the disease, the writings of Jos. Frank,<sup>10</sup> and a variety of papers by Bacot,<sup>11</sup> Lawrence,<sup>12</sup> Crawford,<sup>13</sup> and Johnston,<sup>14</sup> may be consulted.

CASE LV.—*Hydrargyria occasioned by mercurial frictions*. Madame C \* \* \*, thirty-four years of age, came to Paris from the neighbourhood for medical advice, on account of an enlarged state of the lymphatic glands of the neck and abdomen, and a chronic gastric affection. Madame C \* \* \* was recommended by the practitioner she consulted, to rub in half a drachm of the strong mercurial ointment on the insides of her thighs every day. On the fifth day after this procedure was adopted, a very copious eruption of vesicles, each as large as a small pin's head, took place upon the upper and inner parts of the thighs. The skin in these situations was red, hot and extremely itchy. Next day the vesicles became confluent, the skin burning, and the legs stiff; febrile symptoms also set in, and the night was passed without sleep (*Cold baths, cold washes with decoction of althea, lemonade and broth for diet*). On the following or third day a plentiful discharge of yellowish serum took place from the parts affected; the greater number of the vesicles were ruptured, the patient having passed the night in tearing with her nails the districts of skin that were inflamed. Had not the patient been much reduced by the chronic affection of the abdomen, already of several months, standing, I should certainly have taken away blood at this stage. Under the circumstances, I was compelled to be satisfied with recommending the cold bath and emollient lotions. No incrustations were formed on the vesicles; the reddish serous discharge which was poured out abundantly for five days, was absorbed, by the cloths kept constantly applied to the parts. The continual use of the cold bath and the lotions undoubtedly prevented the parts from scabbing over. By the end of the second week the inflammation of the skin had disappeared, and nothing more than a pretty abundant furfuraceous desquamation then took place from the internal parts of the lower extremities. (a)

(a) An instance of the extreme susceptibility of the system to mercury, and to the production of hydrargyria occurs in the following case:

"Mr. R. applied to me, 12th August, 1813, for the cure of a chancre. I had treated him in 1810 for a similar disease, and was then made fully acquainted with his extreme tendency to mercurial erythema. Having premised a tepid bath, and some active purging medicine, I commenced by directing a pill of hydr. acet. gr. ss. and pulv. antim. gr. ij. to be taken every night. On the second day a slight rash appeared on the inside of his thighs; of course the mercury was withheld for a day. No improvement in the chancre attended this eruption. The pills were continued sometimes every day, sometimes every second day, (according to the appearance of the rash,) until the middle of September, when the chancre took an unfavourable turn, and showed a tendency to slough. Then the mercurial medicines were entirely discontinued. The rash having disappeared for four days, the state of the ulcer induced me to recommend the ordinary black wash (calomel and aq. calcis). This had been applied for one day only, when the rash reappeared, and with increased severity. On resuming the mercury on Oct. 3d, I directed hydr. acet. gr. ss., and extr. cicutæ gr. i. No rash appearing, the dose of the pills was doubled: the rash appeared on 11th Oct. After this the dose was cautiously increased to three, and ultimately to four pills per diem. The chancre was very slow in healing, but was completely healed on the first of November. The mercury was continued some

## SCABIES.

Vocab. *Itch, Psora.*

364. Scabies or Itch is an inflammatory affection of the skin, unaccompanied with fever, contagious, and characterized by an eruption of pointed vesicles, transparent on their summits, filled with a viscid and serous fluid, and constantly attended with pruritus. This eruption is liable to appear on every part of the body, but is seen more especially upon the abdomen, about the bends of the different articulations and between the fingers. I must say, however, that I have never seen itch affecting either the face or hairy scalp.

365. *Symptoms.*—When itch has been communicated, the party contracting the disease is sensible a few days afterwards of a slight pruritus in the parts which have been most immediately exposed to the infection. The pruritus is increased through the night by the warmth of the bed, and during the day by indulgence in spirituous liquors, spiced food, and by every cause that produces an afflux of blood towards the surface. A number of small spots or points, elevated, but in so slight a degree as scarcely to rise above the level of the skin, now make their appearance; this eruption usually takes place in children, four or five days after exposure to the contagion; in adults it appears from the eighth to the fifteenth or twentieth day, and in the aged and those affected with chronic diseases, occasionally, a month or more after the infection.

The vesicles of scabies appear first on the parts that have been immediately exposed to infection: the hands in tailors and dealers in old clothes, the breech in infants at the breast, &c. The eruption has at first a rosy red hue in the youthful and florid; but it more usually preserves the common colour of the skin, especially among valetudinarians. It spreads gradually to the parts in the neighbourhood of those on which it first appeared. The proper character of the eruption soon becomes apparent,—small acuminated vesicles are perceived upon every red point. If the vesicles be few in number, they occasion but little pruritus, and long preserve their primary form. If, on the contrary, they be very numerous, the skin between each participates to a certain extent in the inflammation, and the pruritus is greater and less endurable. The vesicles are then most usually torn by the nails, and allow their viscid, serous contents to escape, which, concreting, form small thin scabs, flimsy in their texture and but slightly adherent to the skin. Should the patients have used considerable violence in scratching, the scabs are black and analogous to those observed in prurigo.

In the sanguine and robust, and those addicted to the use of stimu-

days longer, although a slight return of the rash again obliged us to desist for a day occasionally. During this lengthened course of mercury Mr. R's general health continued good. No ptyalism was induced; the gums were not made sore, but the inside of the cheeks assumed a leaden colour, and became a good deal swollen during the last fortnight of the treatment.

“Mr. R. gave me the following account of the effects of mercury on his system. Previously to the year 1806, he had used mercury for cure of a chancre, and did not then experience any but the ordinary effects from the use of this medicine. In 1806, he again had occasion to use it for cure of a chancre, and then he employed it both internally and externally in very large doses. On this occasion it did not affect his mouth; but immediately after he had laid aside the medicine he was attacked with mercurial erythema, which affected him in a very severe and dangerous degree. Since that period (and never before) he has experienced an extreme susceptibility to the action of mercury in producing this rash; for example, a very small portion of mercurial ointment rubbed on the pubes, for the purposes of cleanliness, has more than once produced it. A grain of calomel combined with purgatives has had the same effect.

“In this case I would remark, that the venereal symptom did not improve on the appearance of the rash as it does in less susceptible constitutions. The mercury had not the effect of producing ptyalism, though used for such a length of time. The effects of the topical application of black wash affords the strongest proof of the great susceptibility of this individual.” (Mr. Colles *ut supra*.)

lants, itch, if left to itself, by spreading till almost the whole surface of the body is infected, may give rise to symptoms of considerable severity: the vesicles become more and more violently inflamed, and acquire at length the character and appearance of true pustules (scabies *purulenta*, Bateman); boils, and *accidental* pustules, like those of *ecthyma*, are also occasionally developed in their interstices, under these circumstances.

366. In southern climates, during the spring and summer seasons, in youth, and among individuals of a sanguine and robust constitution, the vesicles of scabies run rapidly through their periods when they are not torn by the nails; their progress is slower in the north, during the winter and autumn, and among the aged and infirm.

Scabies is a disease which left to itself never gets well: it might continue through the lifetime of the individual who should neglect all means for its cure. Its usual duration is from twelve days to a fortnight, when it is properly treated. Occasionally, it may be seen disappearing for a few days under the influence of some intervening acute disease, without the symptoms of the latter being sensibly modified by the circumstance. Sabatier mentions the case of a man labouring under an old and well-marked itch, in whom the vesicles, without any kind of treatment, sank and disappeared on his being attacked with inflammation in both lungs, nor did the eruption appear again until a fortnight after this disease began to yield, and when convalescence was already well established. On the other hand, Rammazzini, Testa, and several others, tell us they have seen hematuria, affections of the heart, and several other serious diseases, follow *retrocession of the itch*. I have not myself met with any similar occurrence, and such cases must be very rare.<sup>1</sup> From a superficial study of symptoms, and the inherent deficiency of our medical nomenclature, consequences have been attributed to the disappearance of itch, which are owing to the retrocession of true eczematous eruptions described under the name of *scabies*.

367. Scabies may be complicated with other cutaneous diseases, and its diagnosis thus be occasionally rendered obscure. Yet is it seldom that other vesicular eruptions are met with on the skin at the same time as itch. When *ecthyma* occurs along with scabies, it is almost always after the employment of stimulating washes or unguents. I have, however, seen vesicles similar to those of *eczema*, and true vesications like those of a blister, on the backs and palms of the hands, when these happened to be the seat of a large crop of scabious vesicles. It is almost always with *papular* eruptions that scabies is complicated. When the vesicles of scabies are widely and plentifully disseminated in a young and hardy individual, they often occasion the development of a lichenous eruption, the papulæ of which are either separately scattered or collected into clusters. Prurigo is also occasionally evolved among subjects who have long suffered from scabies; a circumstance which has given rise to the erroneous supposition that itch occasionally degenerates into a papular disease. When the irritation of the skin becomes excessive, pustules of *ecthyma*, and even furuncles may be seen associated with the vesicles of scabies.

Scabies, when it is extensive and severe, and has continued for a very long time, is now and then seen accompanied or followed by an inflammation of a portion of the mucous membrane of the gastric and pulmonary passages.

In individuals labouring under diseases of the digestive organs or lungs, who contract scabies, the vesicles are flaccid, and either decline or die totally away, when the primary diseases get worse or are temporarily aggravated from any cause,—errors in diet or otherwise.

368. Scabies is scarcely modified in its course by *scrofula* or *sypilis*. In unhealthy subjects the vesicles assume a livid hue, and when they appear congregated in large numbers in particular regions, they are there often seen complicated with *ecthyma cachecticum*.

369. *Causes.*—Scabies is one of the most universally disseminated contagious diseases known; the most momentary contact of the fluid secreted by its vesicles is enough to communicate the infection; it is observed in every climate, during every season of the year, attacking all ages, and persons in every rank of life, without discrimination. It is most commonly observed, however, among the poor and wretched,

<sup>1</sup> Dr. Hahnemann, the noted head of the Homœopathic school, and his disciples, are of a different opinion; they seem to ascribe nineteen in twenty of the ills that flesh is heir to, to *latent psora* in the constitution.—R. W.

and those who are negligent of cleanliness. When it does appear in the families of the affluent, its importation may generally be satisfactorily traced. Sailors, soldiers, work-people, and those who are crowded together in manufactories, prisons, barracks, hulks, &c., are very frequently affected with this disease. Itch is neither an endemic nor an epidemic disease in the usual sense of these words: it is not propagated by causes peculiar to the climate, nor to the situation where it appears; it spreads by the mere effects of contact and want of cleanliness. All tends to show that those *epidemic scabies* of which Frederic Hoffmann and several other writers have spoken, were vesicular eruptions referable to distinct and different genera.

Some pathologists, among others Fabricius Hildanus, Lazarus Riverius and Pringle, have supposed that scabies might be spontaneously developed under particular circumstances, and as *crises* in several acute and chronic diseases. They would persuade us that patients who had long suffered from severe affections, have been cured by the spontaneous appearance of this eruption. I have never met with any instance of this kind; and we may, perhaps, be allowed to suppose that certain vesicular and papular eruptions, such as eczema and lichen, were mistaken for itch, in times when the distinguishing characters of the different diseases of the skin were not very generally known.

Several instances of itch, transmitted from animals to the human species, have been cited; but the greater number of the diseases to which veterinary practitioners have given this name (ox-itch, horse-itch, dog-itch, hog-itch, &c.), are very inaccurately described, and many of the cases of these affections which have been shown to me, analogous to lichen and eczema in their external characters, have still left me in great doubt as to their actual nature; and although their transmission be an asserted fact, which cannot be positively denied, neither can it be satisfactorily demonstrated. M. Mouronval instances several cases, in which the itch was communicated from the dog to the human kind. On the other hand, that skilful veterinarian M. Leblanc, showed Messrs. Sabatier, Littré, and myself, several dogs labouring under the disease called itch, in which we could distinguish a number of small acuminate vesicles, perfectly analogous to those of scabies in the human kind, upon the upper and inner parts of the thighs and various other regions of the body, calling our attention to the fact, that the man by whom these animals were rubbed and tended had not contracted any disease, not only in the present instances, but in many preceding ones; whilst a dog, from having slept on some of the straw which had littered one of the mangy brutes, was seized shortly after with the same disorder.

340. Several authors of modern times, have reported that they had discovered an apterous insect, almost invisible to the naked eye, within the vesicles of scabies, which they have described under the name of *acarus scabiei*. Ingrassias and Jobertus hint at the existence of such an insect; but it is in the *Theatrum Insectorum* of Mousset that it is mentioned with a few particulars for the first time. Hauptmann was the first who published a figure of one of these acari, drawn from nature, as he says, and represented with six feet. Additional observations by Redi seemed to put the existence of this insect beyond doubt: "Whilst under your auspices and led by your views, I was engaged in making experiments on insects, I saw by accident, that the *cirio* was a very small worm, formed under the skin of those affected with scabies, whose bite occasioned extreme itchiness. Having since found, that Giuseppe Lorenzo had adopted the same opinion, I was curious again to examine the fact myself. I communicated my purpose to M. H. Cestoni, who informed me he had several times seen poor women, whose children were affected with itch, draw out, upon the point of a pin, from the smallest pustules, before they were ripe and purulent, a *something*, I know not what, which they crushed between their nails with a slight noise; and he added, that at Leghorn, the galley slaves perform the same kind of office for each other. He says, he does not know for certain, that these *cirros* are actually worms. We, therefore, resolved in common, to satisfy ourselves on the matter; and having applied to a person labouring under the itch, we requested him to point out to us, the parts in which he experienced the most troublesome pruritus. He showed us a number of pustules not yet purulent. One of these I opened with the point of a fine needle, and after squeezing out a little of the

fluid it contained, I drew forth a small white and almost imperceptible globule. This globule we next examined under a microscope, and we found, with all possible certainty, that it was a worm; the form of which, resembled that of a tortoise, of a whitish colour, the back rather of a dusky hue, and furnished with a few very fine hairs; the little animal moved with great vivacity; it had six legs; the head was pointed and armed with two small horns or antennæ, at the extremity of the mouth. Not satisfied with this first observation, we extended our researches to a great many other individuals affected with itch, of different ages, sexes and temperaments, and at different seasons of the year, and always found animals of the same kind, and almost in every watery pustule,—I do not say *all*, for it occasionally happened that we could not find any.

"It is at all times extremely difficult to distinguish these insects on the surface of the body, on account of their extreme minuteness, and of the similarity betwixt their colour and that of the skin. They first insinuate their pointed head, and then move about gnawing and pushing till they have buried themselves completely under the epidermis, where we could easily perceive that they had a kind of covered way of communication between one point and another, so that the same insect occasionally produced several watery pustules; now and then, also, we discovered two or three, either together or very near to each other. We were very curious to learn whether or not these little animals laid eggs, and after much research, we had at length the satisfaction of being assured of the affirmative; for at the very time that M. Isaac Colonello had one of these *cirros* under the microscope to make a drawing of it, he saw a small white egg, scarcely visible, and almost quite transparent, extruded from the hinder part of the animal; it was of an oblong shape, like the egg of a pigeon. Encouraged by the occurrence, we again set about searching for eggs with the greatest attention, and we found many more at several different times; but we never again observed them issue from the body of the animal under the microscope. These *cirros* pass readily from one person to another by mere contact; for, being extremely active, and not always engaged in digging passages under the epidermis, these little animals are often upon the surface of the integuments, and are thus ever ready to attach themselves to whatever they touch, &c."<sup>1</sup>

Morgagni<sup>2</sup> informs us that he had himself made similar observations. "I had occasion," says he "to give my advice to a lady of high rank in my native place. After experiencing several crises towards the end of a severe and long-protracted illness, one completely scabious in its nature was added to the rest, which, coming on suddenly, spread over almost the whole body, but particularly to the palms of the hands, so that she could not sleep by reason of the pruritus. As the vesicles of which this eruption consisted, were filled with serum, and resembled those in which insects are discovered, I caused a servant to open one or two of them, and to take out any thing she might find, after pressing out the fluid, upon the point of a fine needle, and to deliver it to me for examination with some good glasses I had at hand. There was no necessity to look long; the animalcule was found alive, and of the very form which has been delineated by the more modern authors. I then took away another, and still another."

Morgagni<sup>3</sup> also reminds us that Abenzour and several other writers make mention of this insect. Linnæus speaks of it under the names of *acarus humanus subcutaneus*, and of *acarus scabiei*; but having subsequently thought that he perceived the most perfect resemblance between this insect and the cheese mite, he described them together

<sup>1</sup> Obs. sur les cirons ou insectes de la peau des galeux, under the name of Dr. Giovan Cosimo Bonomo, in a letter addressed to the Academy of Paris, in 1687. Published in their Collect. Académ. Etrangère, 4to. t. 4, p. 574, liv. iv., Epist. 55.

<sup>2</sup> De Causis et sedibus morborum, lib. iv., Epist. 55.

<sup>3</sup> "Sunt enim syrones, inquit Abinzoar, pedicelli, Arabibus assoabat dicti, qui subter cutem et ad manus, et crura serpunt: pustulas quoque aqua plenas sub cute, ubi delitescunt, excitant: qua dissecta, prorepunt animalcula tam parva, ut vix visus, quamvis perspicaci, ægre deprehendi possint (J. Langius. Medicinalium Epistol. Miscell., lib. ii. Epist. 42.) Formam quoque ipsorum alius antea fuisse microscopii auxilio non incognitam, cum Borelli observationes indicant a Valschio (Exercit. de vena medinensi), commemoratæ secundum quas syrones testudinum effigies repræsentarunt, tum præsertim Etmølleri illa confirmat syronum observatio quæ Lipsiæ i Actor. Erudit. volumine (A. 1682. M. Sept.) proposita, præterquam alios nominat qui prius viderint, animalcula ipsa sic descripta exhibet, et delineata, ut descriptio, et pictura perfectiores quidem paucis post annis reddi potuerint, sed tanquam novæ prorsus in medium proferri non potuerint." (Morgagni. De Sed. et Caus. morborum, lib. iv., Epist. 55, § 4.)

as mere varieties of one species. De Geer,<sup>1</sup> on the other hand, both in his descriptions and his figures, which are extremely accurate, left no doubt of their generic difference. The existence of the *acarus scabiei*, however, having been called in question, M. Galès,<sup>2</sup> after citing the older observations that had been made upon it, and quoting the more recent authorities of Wichmann<sup>3</sup> and Waltz<sup>4</sup> for its existence, commenced a series of inquiries into the subject in 1812, and assured the world that he had seen more than three hundred specimens of the *cirio* or *acarus* of scabies, which always presented the same form, though not the same number of legs, there being sometimes six, sometimes eight—a variety which he ascribed to variety of development. Many members of the Institute of France, and of the Ecole de Médecine were witnesses of these inquiries of M. Galès, so that the existence of the *acarus scabiei* was generally admitted as a fact. Subsequently, however, Galcotti and Chiarugi of Florence, Bielt, Lugol, and Mouronval of Paris, sought in vain, with powerful magnifiers, and excellent microscopes, for this insect, in a great number of individuals affected with scabies. I was not myself more fortunate than they, in all my endeavours to discover the *acarus*; and the ascertained absence of that insect, in numerous instances, in vesicles in which, if it existed at all, I had been led to expect to find it, as well as the perfect resemblance of the figures given by Galès to the cheese mite, induced me, along with many others, to deny the existence of the *acarus scabiei*. A more careful study of the previous inquiries on this point would have prevented our adopting the erroneous notion we did in regard to the seat of the *acarus*. Mouffet,<sup>5</sup> long ago, remarked that the *cirio* was not found in the *pustules*, but by their sides. Casal,<sup>6</sup> too, had already described the little burrows made under the cuticle by the insects, which are mentioned in the letter of Bonomo. Adams<sup>7</sup> indicates, with the utmost precision, the seat of the *acarus*, and the mode of finding it. Finally, M. Renucci, student of medicine, who had often seen the common people of his native country (Corsica), extract the insect of scabies, and who had himself extracted it repeatedly, very recently (August, 1834), showed the medical practitioners of Paris the mode of discovering it, extracting it before them, and giving them information on the subject almost identical with that which is to be found in Adams. Since this time the existence of the *acarus* is placed beyond a doubt; Messrs. Lemery, Gras and Renucci, each showed me the mode of discovering it, and I have myself extracted several from the skin of individuals affected with scabies. For more ample details on this subject, I beg to refer to the published account of M. Renucci's observations,<sup>8</sup> to the work of M. Raspail,<sup>9</sup> who has given an excellent description and very good figures of the *acarus*, and to the researches of M. Gras,<sup>10</sup> who has made many experiments with the view of determining the share which the *acarus* really has in the production of scabies. (a)

(a) Mr. Wilson (*op. cit.*) records some of these experiments, which may be appropriately enough be introduced in this place.

"Exp. 1.—'On the twenty-eighth of August,' writes M. Gras, 'in the presence of several physicians and students, I placed two living acari on the middle and anterior part of my forearm, and covered

<sup>7</sup> In looking for the insect of scabies, Adams informs us we must not examine the vesicle; but if a line, about a quarter of an inch in length, be seen going off from one of its sides, and at the extremity of this a reddish and in appearance dry and firm elevation be discovered, it is here that with the assistance of a good magnifying glass, the insect may occasionally be found; it is at all events the only place in which it is ever to be expected. (On morbid poisons, p. 299, 4to. London, 1807.) Adams, in mentioning Bonomo, who says he took the insect from the moist vesicle, justly remarks that this assertion renders all his observations suspicious. Adams has given two good figures of the *acarus*.

If, therefore, there be no longer any doubt of the fact that in almost all who are affected with scabies, and who have as yet been subjected to no kind of treatment, a certain number of sub-epidermic furrows containing acari are to be discovered, it is also indubitable that the number of these furrows and of these insects bears no proportion to that of the vesicles. It is, farther, rare to discover these insects on the abdomen and on the groins, where the eruption of scabies is nevertheless very common and very apparent; moreover, scabies is known to continue when no more acari are to be discovered. Lastly, the experiments instituted for the specific purpose of ascertaining whether the *acarus* is truly the *artisan* of the itch, do not appear to me altogether conclusive on the subject.

The *acarus* will be described in the appendix along with the other parasitic animals infesting the human integuments.

371. *Diagnosis*.—The diseases which are most apt to be confounded with itch are eczema, lichen, prurigo, ecthyma, and certain artificial vesicular and papular eruptions.

When scabies occurs alone, and a sufficient number of its vesicles remain unbroken, it is easily distinguished from the *papule* of lichen and prurigo, and from the *pustules* of ecthyma.

Eczema simplex has a greater resemblance to scabies, inasmuch as the general elementary characters of both are the same; but they differ in many essential particulars, and especially in the non-contagious qualities of the vesicles of eczema, which, moreover, are more highly inflamed, and flatter than those of scabies. The diagnosis of these diseases is not so easy, when the vesicles have been destroyed; for if the small and slightly adherent scabs of the itch are very unlike the incrustations of ecthyma, intimately connected with the skin as they are, and the dry or humid excoriations of chronic eczema, they

them with a watch-glass kept in its place by a bandage. On removing the apparatus on the thirtieth, we found two superficial cuniculi (sillons) half a line in length, and at their extremity two little white points, indicating the presence of the acari. Substituting a fold of linen, retained in its place by a piece of adhesive plaster, for the watch-glass, the acari were left undisturbed for six days longer. At the end of this time the white points were no longer perceptible, and the cuniculi having become obliterated, had disappeared.<sup>1</sup>

"Exp. 2.—'On the first of September, I placed seven living acari on my forearm, and covered them with a fold of linen, and piece of diachylon plaster. Four days after, we found four or five well-marked cuniculi. On the sixth of September, two of the acari being extracted from their cuniculi, were found active; they were then replaced. On the twelfth, another animalcule was removed and examined; it was quite lively. On the fourteenth, there was considerable itching, with the development of a vesicle; the cuniculi were two lines long. On the sixteenth, there were several new vesicles near to the cuniculi, but not on their line. On the seventeenth, the vesicles of the previous day had been rubbed off by the linen, but two or three new ones were visible. On the following day I put an end to the experiment, by rubbing some sulphuro-alkaline ointment into the part. During the course of the experiment, I suffered pruritus from time to time.'

"Exp. 3.—'On the ninth of the month, I imprisoned six acari on my ring finger, by means of the finger of a glove. Next day there were two cuniculi half a line long. The *acarus* of one of these burrows was apparent for ten days, the other for three weeks, but after this period they both disappeared. During this interval, I cauterized several suspicious vesicles developed on the same finger, and discovered two new cuniculi originating in acari that had fixed themselves without having been observed. None of the vesicles showed themselves on the line of the cuniculi.'

"Exp. 4.—'I lately placed nine acari in the bend of my left arm, and retained them there by a compress and bandage. Four hours after, I felt considerable pruritus, and the next day perceived four cuniculi. Several days after, some vesicles showed themselves on my forearm.'

"Exp. 5.—'Having placed two acari in the flexure of the elbow of two persons, who expressed their willingness to submit to my experiments, on one, three or four vesicles were apparent on the fifty day, and were accompanied by severe itching. On the other there are two cuniculi, with pruritus, but no vesicles.'"

differ but little from the smaller sized scabs of prurigo, and from those produced by pricking the integuments about the wrists and between the fingers, as is occasionally done by prisoners to simulate the disease of which we are now speaking. Lastly, when scabies has been treated by irritating lotions or unguents, which have produced adventitious eruptions, or when the disease is accompanied with large yellow pustules (scabies *purulenta* Batern), and when the vesicles which characterize it are altered in their nature, and the small scabs which succeed them are mingled with accidental pustules and papulæ, it is only by a careful and minute study of the form and seat of the various alterations presented by the skin—*vesicles, papulæ, pustules, scabs, excoriations, &c.*, that we succeed in ascertaining the number, the nature, and the importance of the different lesions, which together, constitute these complicated cases.

372. *Prognosis*.—If scabies be a much milder disease than is generally imagined, still it very rarely happens, that its appearance exercises the salutary influence on certain acute and chronic complaints, which has been ascribed to it by certain writers.<sup>1</sup> It is still less positively ascertained that its cure, when this event has been followed by untoward symptoms, has actually proved their cause. It is, however, possible, that a severe and old standing scabies, in individuals of weakly constitution, and affected with diseased viscera, may in some sort modify or check the progress of this internal malady; in such cases, it would only be advisable to seek the cure of the scabies in a very gradual manner, and after having established some other species of counter-irritant or drain, in a different district of the skin. On the other hand, I have often had no difficulty in perceiving that unpleasant consequences have been attributed to the discussion of itch, which have truly been due to the disappearance of eczematous and lichenous eruptions, improperly designated under the name of scabies.

373. *Treatment*.—In old standing cases of scabies, when the vesicles appear crowded together in great numbers, and are attended with violent inflammation of the skin, or with adventitious eruptions, it is advantageous, if the constitution will admit of such practice, to begin the treatment by a bleeding from the arm, by soothing lotions, and occasionally by simple baths. But when the disease is uncomplicated and of recent date, its cure is easily obtained without any preparatory steps by local means, of which experience has proved the general efficacy.

Frictions with the sulphur ointment (R. Adipis suil. lb. 1; Sulphur. sublim. lot. 3viii); or with this ointment, combined with sub-carbonate of Potash (R. Adipis suil. 3i; Sulphur. sublim. drm. ii; Potassæ subcarb. drm. i); or with the powdered sulphuret of lime, usually accomplish the cure of scabies within a fortnight. The sulphur ointment may be used in doses of two ounces daily, being rubbed morning and evening, over the whole of the parts affected with vesicles, so long as any remain visible. When the compound sulphur ointment is used, and it is the one I generally prefer, the patient's skin must be well cleansed with soap and water, after which, one ounce of the ointment is to be diligently rubbed during half an hour over the whole surface of the body. The rubbing is to be repeated at mid-day, and again before the patient lies down for the night, the treatment being continued on the following days in the same manner. In this way patients are often cured on the second or third day, and a very large proportion before the seventh. The course of friction is to be wound up with a warm bath, and an abundant use of soap to cleanse the skin.

Helmerich was in the habit of prescribing four ounces of the compound sulphur ointment in eighteen hours, and repeating the same quantity next day.

Such repeated inunctions have unquestionably the advantage of destroying the contagion rapidly, but they have the inconvenience of frequently causing artificial vesicular and papular eruptions, which compel us to suspend our treatment. Helmerich's plan is nevertheless the best when our object is the speedy recovery of a great number of individuals affected at the same time, and who, from their situation, are necessarily much in contact, such as soldiers, prisoners, the members of a large family, &c. I usually recommend the same plan to

the work people and artisans who apply as out-patients at the Dispensary of the Hôpital de la Charité. I occasionally employ sulphureous baths in conjunction with the compound sulphur ointment, and find the plan extremely efficacious.

In the plan of Pyhorel it is enough to add half a drachm of the sulphuret of lime to a little olive oil, and with the mixture to rub the palms of the hands during a quarter of an hour night and morning. Obstinate cases of scabies are by this means generally cured at the twenty-fourth or twenty-fifth friction. I, however, greatly prefer to this partial method of inunction, the plan by which the specific is applied directly and at the same time to the whole of the affected surfaces.

Artificial or natural sulphureous baths are particularly applicable in the cases of children, but the treatment carried on with these alone is expensive, twenty baths at least being required to accomplish the cure. Sulphureous washes, particularly one composed according to either of the following receipts: R. Potass. sulphuret. 3i; Aqu. lbs. iij; or R. Acid. hydrochloric. (muriatic) 3i; Aqu. distil. lb. i; an ounce of one of these mixtures added to four ounces of warm water and applied to the affected parts usually effects a speedy cure. These washes do not soil the linen and clothes of the patients like ointments; but they prove irritating to the skin of many persons, causing vesicular and papular eruptions which occasionally require bleeding and the warm bath before they are subdued.

*Alcoholic saponaceous washes* are less certain in their effects than sulphureous frictions and lotions, and may occasionally be recommended to the wealthy who are anxious to conceal the nature of their malady, or who show a repugnance to the use of sulphur in any of its forms or combinations: I make use of them but rarely.

*Sulphureous fumigations* which are employed in some hospitals are not attended with expense, leave no unpleasant smell, and do not soil the linen; but the long continuance of the treatment necessary to relieve the disease, more than counterbalances these generally insignificant recommendations.

I cannot enter into any long details concerning the method of treating complications of scabies with eczema, prurigo, lichen, ethyma, &c. Each of these diseases of the skin requires appropriate remedies, which either have been or will be made known in the course of this work. When such complications appear at the beginning of the disease, it is a good plan to use the simple and the sulphureous bath alternately; if taken every day, the latter might increase the concomitant affections, an effect which I have frequently observed when they were administered on account of varieties of scabies. When these diseases, or other artificial inflammatory affections of the skin, are set up towards the end of the treatment, we must be on our guard against taking such adventitious affections for *modifications or degenerations* of scabies: they would only be made worse by persevering in the use of sulphureous remedies.

When the vesicles of scabies have been made completely to disappear, we must take measures against their return. With this view the clothes of the patient, especially those that are of wool, must be disinfected by exposing them to the fumes of the sulphureous acid gas; the linen should be changed frequently, and the greatest attention paid to general cleanliness.

375. Having now made known the most successful and economical methods of treating scabies, I shall only say further in connection with the curative plan, that the inunction of oil, as recommended by M. Delpech, is less efficacious than the preparations of sulphur; and that the use of various *acid ointments and washes*, the bases of which are nitric acid and mercury, recommended for the cure of scabies, have occasionally produced salivation and disturbance of the digestive organs. A sulphuro-saponaceous liniment, (a) which has also been praised as effectual, I have seen followed by sweating, smarting, general uneasiness, and the development of artificial vesicular and papular eruptions. In fine, many other preparations such as the

proto-ioduret and the deuto-ioduret of mercury, have appeared to me rather injurious than beneficial in this disease. I conclude by stating, that I have found the plan recommended by Helmerich, which I usually follow, to be the safest and most efficacious of all. (a)

### Historical Notices of the Disease.

376. It has been said and repeated again and again, that the Greeks described the disease we call itch, under the name of *ψωγα*. This assertion is incorrect. By this word they designated scaly diseases in a general way, and by no means a *vesicular eruption, susceptible of transmission by contagion*. I should also state, that if in works published in the Latin language since the revival of letters, the itch is designated under the name of *scabies*, and this denomination is even applied to the disease in this place, the word was not used originally in the sense now attached to it. The description in which Celsus makes use of the term *scabies*, is much more applicable to confluent and excoriated lichen than to itch. "*Scabies verò est asperitudo rubicundior ex quâ pustulæ oriuntur, quædam humidiores, quædam sicciores. Exit ex quibusdam sanies, fitque ex his continuata exulceratio pruriens, serpitque in quibusdam citò. Atque in aliis quidam ex toto desinit, in aliis verò certo tempore anni revertitur. Quò asperior est, quòque prurit magis, eò difficiliùs tollitur; itaque eam quæ talis est *ὑγίαν* id est *feram*, Græci appellant," etc. There is no mention whatever in this obscure passage of an essential character of itch, which could neither have been overlooked nor omitted, namely, its *contagious nature*; further, itch never terminates spontaneously. It does not recur at certain periods of the year, and so on. In no other way, therefore, but by interpreting this passage amiss, can it be maintained that Celsus knew and had described the itch. Galen, under the title *ψωγα*—translated into the Latin, *scabies*—describes several squamous alterations of the skin, especially of that of the eyelids. There is nothing to authorize the assertion, that this writer was acquainted with the vesicular disease termed *itch* in England, *gale* in France; for if, in the following passage from the treatise *de pulsuum differentiis*, lib. iv. cap. 1, "*sed ut psorâ et lippitudine qui proprius accidunt, quidam corripuntur inviti*," it be said that *psora* may be transmitted by contagion, in connecting it with *lippitudo*, the author makes us suspect that he was discussing a disease of the eyelids, and not an eruption scattered over the fingers, wrists, bends of the arms, axillæ, &c.; and in the passages particularly devoted to the history of the different species of *psora*—rendered *scabies* by the translators—not one of them is mentioned as contagious.<sup>1</sup>*

In the Latin translations of Avicenna the word *scabies* where it occurs, does not seem applicable to the *itch*. Avicenna does not speak of contagion; he says, however, "*Et non accidit plurimum nisi inter digitos, quia sunt debiliores.*"

Guy de Chauliac is the first who points out the essential character of itch in an unequivocal manner: "*Scabie*," says he, "*est une maladie contagieuse.*" Fernelius and Paré, less accurate in their descriptions, have omitted this important feature of the disease, of which, however, Vesalius, Forestus and Van Helmont have taken notice.

Among the numerous diseases of the skin, which Hafenreffer<sup>3</sup> comprises under the title *Scabies*, he does not describe *itch*.

Willis does not separate it with sufficient care from other pruriginous affections, but he was perfectly aware of its contagious nature, and of the value of sulphur in its cure.<sup>4</sup> Willan and Bateman<sup>5</sup> have

(a) In general, it will be most prudent to administer sulphur internally, in conjunction with bitartrate of potassa, or the sulphuret of potassa, with a neutral salt in solution—at the same time that sulphur is used externally. I have cured scabies by blue mass and laxatives without recourse to sulphur in any form. Camphor dissolved in oil, in the proportion of one drachm to an ounce, answers, as we learn from Mr. Wilson, every purpose of eradicating the disease.

<sup>1</sup> Novus index in omnia quæ extant Cl. Galeni opera. fol. Basilæ, 1562—Art. Psora, Scabies.

very unnecessarily multiplied the species of this disease. M. Fourrier<sup>6</sup> has given a detailed history of the various methods of treatment, and Bielt<sup>7</sup> has devoted himself to demonstrating its constantly vesicular primary form. M. Mouronval has collected a great number of particular cases, and has given the results of his experience on the majority of the curative plans which have been proposed, especially on the effects of fumigations and alcoholic lotions; as also an account of the researches of M. Lugol on the *acarus scabiei*.<sup>8</sup>

M. Hurtel d'Arboval<sup>9</sup> has collected some observations on the itch of domestic animals; but these are still very imperfect.

Observations or cases of *simulated* itch have been published by M. Fabre,<sup>10</sup> and remarks on the *repulsion* of this disease<sup>11</sup> and on different methods of treating it, as by the liniment of the sulphuret of lime,<sup>12</sup> the compound ointment of sulphur and subcarbonate of soda,<sup>13</sup> the use of oil alone,<sup>14</sup> or the chlorate of lime,<sup>15</sup> the root of the plumbago europ,<sup>16</sup> &c., may be found considered in separate treatises, and various periodical publications.

### MILIARIS SUDATORIA, VEL SUDOR MILIARIS.

#### Vocab. Miliaria, Sudor. [Sudatoria.]

377. Sweating miliaria is an eruptive and contagious febrile disease, which almost always appears as an epidemic, and is characterized on the exterior by a copious and continued sweat, and, generally, by the eruption of small, rounded vesicles the size of millet-seeds.

The symptoms which precede or accompany the eruption may be complicated with those of other diseases; hence arise diversities in the severity, and a host of individual peculiarities in the character of the malady, which may, however, be regarded as assuming two principal forms, *mild* or *benign*, and *malignant* sweating miliaria.

378. When the disease appears in the milder form, the attack is often proclaimed by a feeling of lassitude, pain over the eyes, and loss of appetite; frequently, however, the patient is seized at once without any premonitory symptoms. In the epidemic which raged in the department of the Oise, in 1821, many individuals who had gone to bed well awoke labouring under the disease, their bodies bathed in sweat which never disappeared till their death or convalescence. Occasionally an almost imperceptible degree of fever, a burning heat, or a feeling as if a vapour were passing over the whole of the limbs, and still more frequently, a sense of constriction about the epigastric region, precedes by some hours, or by some minutes or seconds only, the appearance of the *sweat*, or rather the *hot vapour*, which, steaming from a few districts of the body at first, is soon exhaled from the entire surface. The mouth is clammy and the tongue is covered with a foul white, or, more rarely, yellowish fur. The inclination for food is gone, or is at least exceedingly moderate. The urine frequently preserves its natural characters. The bowels are usually confined during the whole course of the disease. The pulse is good in many cases, and only becomes frequent at the period of the eruption. The respiration seems troubled or oppressed in the same manner as it is in an atmosphere the temperature of which is excessively high. The encephalon and its dependences, the organs of sense, and those of generation, do not seem to be affected. This state continues with slight variations through the second, third and fourth days of the disease. It is on one of these days, usually the third, that after some slight sensation of tingling, a miliary eruption makes its appearance

upon the skin, spreading from about the sides and nape of the neck, where it usually shows itself first, to the ears, the mamma in the female, the back, the insides of the arms, the abdomen, and the inner aspects of the thighs and legs. It may be evolved generally and rapidly, or partially and slowly, be circumscribed or progressive, come out suddenly or in succession, and be distinct or confluent. The vesicles which characterize this eruption are of the size of millet-seeds, pearly and diaphanous, and more distinct when the skin is put upon the stretch, and they are seen obliquely; they are also easily felt by the point of the finger. These vesicles are often intermixed with red and inflamed papulæ, which make the skin look like shagreen; lastly, true bullæ may appear accidentally on different regions of the body.

The duration of the vesicles individually, is from two to three days. They dry up and are followed by a desquamation of the cuticle greater or less in amount.

More constant in its occurrence than the eruption, the sweating is always copious, and accompanied with a peculiar odour,<sup>1</sup> which I have compared to that of rotten straw. The sweating begins with the morbid symptoms, and continues profuse during the whole course of the disease. It is not attended with any considerable heat of surface.

The whole of the symptoms decline by degrees, and disappear completely on the eighth, the ninth, or the tenth day.

2d. The *malignant* form of this disease appears to be induced by various concomitant and accidental circumstances: in one case it is a severe inflammatory affection of the stomach and intestines; in a second, true inflammation of the lungs, or of the bladder, which is set up; in a third, the *nervous* is the system which is implicated, and then we have delirium, coma, and convulsions, which speedily prove fatal. When the digestive organs are affected, the patient complains of an acute girding pain in the epigastric region; the spasm extends to the organs of respiration, and occasions the most distressing anxiety; the patients give vent to long-drawn sighs, complain of a sense of weight upon the chest, of a feeling of suffocation, of violent and unusual pulsations in the region of the stomach, synchronous with those of the heart, and of such general and indescribable uneasiness as makes them fear for the worst. These distressing symptoms occasionally appear in the very outset of the disease; they recur frequently during its course, and make their attack with particular violence on the third or fourth day, immediately before the appearance of the eruption. From the commencement of their illness, some patients suffer from vertigo and violent headache, complain of nausea, and make repeated efforts to vomit; or the countenance is flushed, the eyes are starting and injected, the temporal arteries throb, the pupil is contracted and immovable, and the patient sinks within a few hours, comatose, or convulsed. In other cases, a deep-seated pain in the chest, a diminution of its sonorousness, a crepitating rattle, or a blowing noise in one or several lobes of the lungs, oppression of the breathing, which is short and quick, frequency and fulness of the pulse, and sanguinolent expectoration, proclaim a concomitant inflammation of the lungs. Lastly, some patients complain of difficulty in passing their urine, and of deep pains in the hypogastric region, symptoms which, together with the high colour and deficient quantity of the excreted fluid, give unequivocal evidence of an inflammation of the bladder.

The malignant form of miliary sudor occasionally proves fatal within twenty-four or forty-eight hours; the disease occasionally runs its course within the week; more commonly, however, it does not terminate till after the lapse of a fortnight, and it may even extend beyond the third week.

<sup>1</sup> This odour has been likened by M. Menière to that of water slightly impregnated with chlorine, or to that of the evacuations of patients labouring under cholera. "The smell of rotten straw only struck him in those patients who were lying on indifferent bedding, of which an old palliase formed the principal part (Archives Génér. de Médecine, t. xxix. p. 100). I have, however, felt the peculiar odour in question very distinctly, from the persons of those patients who were laid on *very comfortable* beds, particularly from that of the Mayor of Cirès les-Mello. Other writers as well as myself have also said that it was *ascenscent*, and *very similar to that of rotten straw* (Schahl and Hesser). Lepeque-de-la-Cloture, says, that the sweat has a *rotten sour* smell (*aigre pourri*); others have characterized it as mephitic and insupportable (Pujol). It is certain, therefore, that the odour in these cases is always *peculiar* and very unpleasant.

Epidemic miliary sudor much more frequently occurs without any eruption than epidemic measles, scarlatina, or small-pox; the absence of eruption is indeed a much more frequent phenomenon in this than in any of the other forms of eruptive fever. In the epidemic of 1821, the eruption was wanting in a great number of the individuals attacked (*febris sudatoria*).

During convalescence from this affection, secondary diseases are more rarely observed than in recovery from any of the other eruptive diseases. When they do occur they are usually gastro-intestinal affections, and they occasionally consist in eruptions of boils, or of pustules of ecthyma.

379. *Alterations of structure*.—From the small number of post-mortem examinations that have been made of the bodies of individuals who have died of this disease, it would appear that when the fatal event is preceded by anxiety, pain, and a sense of heat or burning in the epigastrium, the mucous membrane of the stomach is red, and its capillaries are injected. This state of increased redness is continued into the duodenum and small intestines, where, however, it becomes less apparent. When the death had been sudden and was preceded by nervous symptoms, the vessels of the brain were found injected; in those cases in which the catastrophe was less rapid, a quantity of serum, greater or smaller in amount, was invariably found in the ventricles of the brain.

These inquiries, however, are still very incomplete.

380. *Causes*.—In France this disease has principally been observed in Picardy, Languedoc, Normandy, Berry and Alsace. It commonly prevails as an epidemic. The epidemics denominated *sweating sickness*, which occurred in England in 1485, 1506, 1507, 1588, at Guise in 1759, at Beauvais, in 1750, at Hardevilliers, in 1773, &c., all differed essentially from the disease we are now investigating, in the important circumstances of duration and mortality. (a) The sweating disease with miliary eruption which prevailed in the department of the Oise in 1832, was much less extensively felt than that of 1821, and appeared to be modified by the reigning choleric constitution. In the epidemic of 1821, the theatre of its attacks was bounded almost on every side by extensive forests, and lay between north-west and south-west, the direction in which its ravages extended.

Excessive heat, and an atmosphere surcharged with electricity, have in some districts been observed to precede the appearance of the disease. It is, however, evidently endemic in certain situations, and may occur sporadically in the places where it has prevailed as an epidemic. Several well-informed physicians have confounded the disease with inflammation of the gastric and intestinal mucous membrane,<sup>2</sup> or with the eruptions of sudamina, which are observed during several acute diseases.

The miliary sudor only appears between the 43d and 59th degree of northern latitude. Moist and shady situations seem favourable to its development; but it is contagious, and once engendered spreads in the same manner as measles and scarlet fever. It does not appear that it can be propagated in any other way: several practitioners have inoculated themselves with impunity with the fluid of its vesicles.

No age gives immunity from the attack of this disease, but adults and females seem more especially obnoxious to it. During the epidemic of 1821, the number of those affected was so much the more considerable in each district, as it lay nearer to that which was first attacked, as the situation was unhealthy, and its poor were numerous. Mr. Menière ascertained that a great many of those who had been seized, during the epidemic of 1821, were again attacked and died during that of 1832.

381. *Diagnosis*. To make the peculiar characters of the miliary sudor stand prominently forward, it is enough to contrast it with the other eruptive fevers, and the diseases which, like it, are proclaimed on the surface under the form of vesicular eruptions.

In the sweating miliaria there is profuse and incessant perspiration, and generally an eruption of vesicles upon the skin, which appears

(a) The author, in a subsequent paragraph (384), insists, however, on the unquestionable analogy that subsists between the two diseases.

<sup>2</sup> See the critical notices of my work, "sur l'épidémie qui a régné dans le département de l'Oise, en 1821," inserted in the annales de la médecine physiologique. Janvier, 1823; and in the Journal général de médecine, t. lxxiii. p. 341.

like shagreen to the touch. In measles we have bronchial affections, and small red patches disposed in arcs of circles, separated by intervals in which the skin preserves its natural colour. In scarlet fever we have inflammation of the tonsils, and a bright, nearly uniform, raspberry red colour of the integuments. Neither of these diseases is accompanied by the excessive and continued perspiration which we remark in the miliary sudor.

The vesicles of the different varieties of herpes are larger than those of the miliaria; they also occur in clusters, and are confined to a single region of the body. Sudamina appear in several diseases, and do not form any morbid individuality, if the expression may be allowed; they are observed accompanying the furuncular inflammation of the bowels, rheumatism, phthisis, the milk-fever of puerperal women, &c. Acute eczema is not attended with sweating, and in its progress has no character in common either with miliary sudor or any of the eruptive fevers. The vesicles of eczema are far more minute, and those of chicken-pox more prominent and much larger than those of the sudor. As to those who would confound the miliary sudor with a gastro-enteric affection, their hypothesis brings to mind that according to which measles and scarlatina are maintained to be, the one a bronchitis, and the other an angina reflected upon the skin.

382. *Prognosis.*—The miliary sudor, in its simple state, is a perfectly mild disease. The fever and the gastro-intestinal symptoms which precede and accompany the sweating and the eruption; the affections of the brain, lungs and bladder which may intervene at different periods of its course, combined with the general character of the prevailing epidemic, render our prognosis unfavourable in different degrees, according to the severity of the symptoms.

However alarming the first symptoms may have been, if they decline or yield after the eruption has appeared, the issue of the disease will generally be favourable.

During the epidemic of 1821, the eruption was independent of any irritation of the stomach. I have seen it confluent without violent previous pain of the epigastric region, nausea, or redness of the tongue; and I have several times met with all these symptoms in patients who suffered from profuse and incessant sweating, without any eruption whatever. It was also independent of the sweating, seeing that it did not invariably succeed even the most profuse epidrosis.

Death often closely follows shriveling of the vesicles; and occasionally occurs very suddenly, at times,—even in a more unexpected manner than in the other eruptive fevers.

In the epidemic of 1821, the greatest mortality was observed among individuals of the ages of thirty-two, twenty-four and twenty-six. The mortality among males was one in thirteen and 3–11ths; among females it was not higher than one in twenty-eight and 7–10ths. Daily observations showed that the chances of death were greater at the beginning and decline of the epidemic than during the period of its greatest prevalence. Among certain trades or professions,—the makers of mattresses, bakers, postillions, smiths and farriers, the mortality was greater than among individuals exercising other callings. The mortality was very various in different districts or townships: at La Chapelle the proportion of those who died to those who were attacked was as one to two, whilst at Neuilly-en-Thel, it was not more than in the ratio of one to one hundred and eighteen.

383. *Treatment.*—Were isolation practicable it would unquestionably be useful in the epidemic sudor; the advantages of temporary emigration are undeniable; any other preservative means are uncertain in their efficacy.

Diluents, and the application of a few leeches to the epigastric region or to the feet, if there be pain in the stomach or head, answer in the milder cases of the disease, in the treatment of which, indeed, the purely expectant method may generally be recommended.

General blood-letting, either alone or combined with powerful irritants, such as mustard-plasters, and blisters, has been occasionally used with success, when the brain appeared about to be seriously affected. I know not whether the temporal artery has ever been opened under these circumstances or not. These cases often prove rapidly fatal, and this termination has not seemed to be even delayed by the repeated abstraction of blood from the general system, during

the period when the cerebral symptoms were threatened. In the miliary sudor, as in variola and scarlatina, these nervous phenomena are occasionally independent of actual inflammation.

After the eruption has appeared, blood-letting is always injurious. I have been witness to the fatal effects of repeated bleedings, practised with the view of cutting short the disease, which, in these cases, when it did not end fatally, nevertheless went through the whole of its usual phases.

When the eruption in this disease disappears suddenly, its return ought to be solicited by every means,—dry frictions, urtication, mustard cataplasms, &c.

Sudorific drinks may be recommended in some particular cases to increase the determination to the skin, or to recall the eruption should it have disappeared; it is not, however, in general, advisable to pursue any measures calculated to increase the sweating.

Pujol not only recommends patients labouring under this complaint to be lightly covered, but would even have them rise and expose themselves to the open air. Messrs. Schahl and Hessert inform us, that they have observed good effects from cold bathing, and the aspersion of cold water. I did not try this measure in the epidemic of 1821; but I have seen the spasm and pain of the epigastrium which precede the eruption, cease after the application of cloths dipped in cold water to this region.

Emollient cataplasms and glysters allay the pains complained of in the abdomen, and lessen the dysuria. The general warm-bath, or the hip-bath, is often used with success in appeasing the irritable state of the intestinal canal which occasionally continues during the convalescence of the patients.

In the epidemic of 1821 many practitioners tried the tartrate of antimony and the ipecacuanha, during the first stage of the disease, expecting, by these means, to render its subsequent progress milder and more regular. As a general and exclusive mode of treatment, this practice is really less efficacious than the simply expectant or moderately antiphlogistic system.

Aperients at the period of convalescence have been recommended by several practitioners. They were little used in the epidemic of 1821, and I do not recollect to have heard a single fact quoted which certainly proved their utility.

Lastly, there was a practice prevalent in the earlier periods of the epidemic of 1821, which nothing tended to justify, and which was soon abandoned; this was the keeping the whole of the patients, without distinction, constantly awake, in the intention of preventing *seizures of the brain*.<sup>1</sup>

Patients ought to be deprived of nourishment of every kind during the four or five first days of this disease, and confined exclusively to diluents. It may even be found necessary to continue this severe system of low diet so long as the seventh or eighth day. Patients may then be allowed a little veal or chicken broth, and the quantity and consistency of the food may be gradually increased afterwards. Almost all the relapses I observed, during the epidemic of 1821, were owing to indigestion, or the occurrence of gastro-intestinal inflammation.

It is almost needless to add, that due attention to cleanliness, to the renewal and purification of the air, to a regimen adapted to an acute disease, and a judicious employment of moral means ought in this, as in all other diseases, to be brought in aid of the medical treatment.

#### *Historical Notices and particular Cases.*

384. Hippocrates, Galen and Avicenna make mention of miliary spots or elevations which occurred during the course of certain febrile diseases; but the characters of these eruptions are too indefinitely given to enable us, at the present day, to decide whether the ancients were acquainted with the miliaris sudatoria or not, or whether their observations refer to the papular eruptions of dothineritic affections, or to the sudamina occasionally seen on the skin, in a number of acute and chronic diseases.

<sup>1</sup> I remark, as a very singular circumstance, that Rush, in his account of the yellow fever, as it appeared in the city of Philadelphia in the year 1793, p. 35, regards sleep as rendering the body more peculiarly susceptible of being influenced by the epidemic.

I conceive that I have, in another work,<sup>1</sup> demonstrated the unquestionable analogy that subsists between the sweating-miliaria of our own days, and the epidemic sudor, or sweating sickness, which ravaged England in 1485, 1506, 1517 and 1528.<sup>2</sup> The want of miliary vesicles in the old English disease, does not necessarily make it different from the disease we are now discussing, a great number of the patients attacked in the epidemic of 1821 having had no eruption.

Some choice and selection are necessary from among the cases and memoirs recently published on miliary sudor; many of them refer to *sudamina*, others to the accidental vesicular eruptions occasionally observed in puerperal women; others to the spots which accompany dothineritis, and so forth.

I confine myself here to pointing out several works in which the epidemic miliaria is described with accuracy,<sup>3</sup> and for farther details, I beg to refer to the treatise I published in 1821, and to the observations of Messrs. Menière, Hourman, Pinel-Grandchamp and Moreau,<sup>4</sup> on the epidemic which prevailed in the year 1832, in the department of the Oise.

CASE LVI.—*Sweating-miliaria of a mild character.* L. A. was seized on the 6th of August, 1821, with the sudor, shortly after the recovery of his wife. This patient presented a striking instance of the occasional mildness of the disease. When I asked him why he had sent for me, he answered that he "was sweating profusely, but had no complaint to make." He had taken to his bed after a slight sensation of uneasiness, and having several times felt chilly for an instant. His face was flushed, and when questioned closely, he complained of slight headache; he was drenched in a profuse and fetid perspiration; the tongue was white and thickly furred; the epigastrium was not tender, even on pressure being made; belly supple, urine natural, thirst not very pressing, in spite of the copiousness of the perspiration; pulse soft, giving sixty-two pulsations per minute; breathing natural; faculties of the mind untouched. (*Veal broth, infusion of borage sweetened with honey, for drink.*) August 7th. The patient, whose fears I had dissipated on the presumed danger of yielding to sleep, had slept quietly for several hours during the night. The sweating was as profuse as ever, but the heat of surface was neither excessive nor troublesome; the tongue was still covered with the same whitish fur; its edges were neither red nor inflamed; bowels confined, no pain of the abdomen, slight sense of oppression, pulse natural. 8th. Same state. 9th. The patient has had a good night, but complains of oppression, and a feeling of weight at the pit of the stomach; he sighs deeply at intervals, as if he would cast off some load that weighed upon the chest. There is no complaint made of throbbing or sense of burning in the epigastrium. The pulse is full, beating seventy in a minute; the skin is hotter, and the patient complains of itching over the loins and chest; a considerable number of red, conical, miliary vesicles are discovered on the neck, chest, and upper extremities, between which the skin preserves its natural colour and appearance. The pain of the epigastrium having increased, six leeches were applied to this region. The night of the 10th was more restless than wont, but the pain of the epigastric region and the sense of oppression had greatly declined since the appearance of the eruption and the application of the leeches. The bowels were still unrelieved; the urine was healthy; the patient was

without fever, although feeling considerable thirst; the vesicles, rather numerous on the arms, were thinly scattered on the legs and thighs. (*Beef tea.*) 11th. Several hours of tranquil sleep through the preceding night; sweating less; appetite beginning to revive; the vesicles gone. (*Soup.*) 12th. Patient well and able to rise. Though complaining at first of considerable weakness, he regained his strength very rapidly.

CASE LVII.—*Miliaris sudatoria; vomiting, delirium.* A. H., eighteen years of age, of a hardy constitution, had complained for some days of a want of appetite and a disinclination to labour not usual with him. On the morning of the 1st of August he felt a violent headache, sense of constriction about the epigastrium and nausea. He was then seized with vomiting, and with profuse and incessant sweating. The patient was greatly alarmed, his master having died of the same disease with which he now felt himself attacked, a short time before. August 2d.—The sweating continues; the face flushed, eyes sparkling, tongue covered with a thick yellow fur, pulse full, hard and frequent, furious delirium during the night (*fourteen leeches to the epigastric region*). 3d.—Excessive restlessness, the patient delirious and managed with difficulty (*a large bleeding from the arm, mustard poultices to the legs*). The ensuing night pretty tranquil; the sweating continues; the anguish and depression of the patient are extreme. He thinks nothing can save him from death. (*Sinapisms to the legs, and venesection in case the paroxysm returned.*) 4th.—The patient was not bled; the sweating continued as copious as ever; the eruption begins to be perceived on the fore-arms, hands and neck; throbbing and flushes of heat in the epigastrium, which is tender to pressure; other symptoms much the same. (*Glysters, six leeches to the epigastric region.*) 5th.—Sweating still continues; the eruption now appeared successively on the neck, arms, and thighs, chest and face. It is so confluent that the whole of the vesicles might be said to be in contact; they are more particularly crowded on the hands and wrists. Of all the patients I had seen, none presented so copious an eruption as A. H. 6th.—Apyrexia, skin rough to the touch, tongue less furred; the urine deposits a copious white sediment. 8th.—Symptoms still declining, no fever, evident desquamation of the cuticle, tongue almost quite clean, urine depositing, appetite returning (*veal and chicken broth, plain soup*). 9th.—Patient convalescent; the pulse is remarkably slow, only beating forty-five in a minute. The patient is able to rise, and feels comfortable. His final recovery was slow.

CASE LVIII.—*Sweating miliaria, hæmoptysis, dysuria.* M. B., jun., on the 25th of July, applied fifteen leeches to his legs in the hope of preserving himself from the sweating disease which prevailed around him. On the 6th of August he had the first symptoms of the disorder; supra-orbital headache, general lassitude, constriction of the epigastrium followed a few hours afterwards by the breaking out of a profuse and fetid sweat which drenched the whole surface of the body; mouth clammy and unpleasant, tongue white and furred, little thirst, slight pain of the epigastrium, which began after the sense of constriction went off, belly soft, bowels constipated, urine not much changed, pulse full, but not hard (seventy-five beats per minute); respiration natural, although the patient complains of a load on the chest, which on percussion is found to be everywhere resonant. (*Veal broth and lime-tree flower water sweetened with honey for drink.*) August 7th.—The sweating continues; the tongue is still white and coated, but moist; the thirst is by no means troublesome; the other symptoms are much the same, except that the sense of oppression about the chest becomes so great that the patient is truly agonized. This state of suffering was undoubtedly increased by the fear the patient expressed of sinking under a disease which he had seen commit such havoc around him. 8th.—The patient had passed a restless night; in addition to the symptoms already described he complained of a general tingling over the body, which was more especially troublesome in the region of the loins; in the course of the evening a great number of red miliary vesicles, scarcely rising above the level of the skin, made their appearance upon the loins, nape of the neck, and arms. The fingers passed over these parts received precisely the same impression as that conveyed by the surface of shagreen. The eruption came out rapidly; the patient was very restless during the three or four hours that preceded its appearance;

violent pain in the head, anxiety about the præcordia, burning heat of the epigastrium, sense of oppression in the chest, and constriction of the stomach; the pulse was full, the sweating profuse, accompanied by a marked increase in the temperature of the surface. (*Antiphlogistic drinks; eight leeches to the epigastric region.*) 9th.—The eruption had spread over the whole surface of the body; it consisted entirely of reddish, slightly transparent, miliary vesicles; the fever ran high, the heat of skin was considerable; but the painful symptoms about the chest and abdomen had sensibly abated, and the patient expressed less solicitude about the issue of his illness. Between one and two o'clock in the morning, M. Pariset (who had attended the case along with me from the first), and I were summoned from our beds to see the patient who had been seized with a spitting of blood. We obeyed the call immediately, and found the patient much in the same state as we had left him at last visit, but extremely agitated, and declaring he should certainly be suffocated; he had had several fits of coughing, and in the matter expectorated there appeared a small quantity of florid blood not amounting to a tablespoonful in all. The chest on percussion carefully practised, sounded well throughout the whole space occupied by the lungs. The patient could fetch a long breath without pain. We attributed the new symptoms to a determination of blood towards the mucous membrane of the bronchi, which probably commenced but a few hours back; a period at which the patient had felt what he called an *accession*, ascribable to no particular cause. I immediately bled him to the extent of eight ounces; the pulse was scarcely weakened by this operation; cataplasms of linseed meal and flour of mustard mixed, were applied to the feet, and the cooling drinks were continued. 10th.—The blood withdrawn was buffy; the serum scanty; the patient had slept; the pulse was soft and less frequent, and a long breath could be drawn without causing cough or any uneasiness in the chest. The tongue was still white; the constipation continued; the vesicles were less numerous; the sweating still profuse but without heat of surface. During the course of the day the patient began to complain of a deep-seated pain in the hypogastrium; this was increased by pressure and accompanied by frequent calls to make water, with pain in the bladder on passing the urine, which was only excreted in very small quantity, high coloured, and loaded with salts,—if such an inference might be drawn from the amount of deposit let fall in the chamber utensil. These new symptoms were met by fomentations and emollient cataplasms to the hypogastric region, and by mucilaginous glysters. Next day almost the whole of the bodily functions appeared to be restored to their natural condition; the sweating was transitory and not very copious; no desquamation of the cuticle had taken place, and the vesicles were disappearing. The patient took some beef-tea with bread in it, during the course of the day. By the 12th there were no longer any traces of the disease, and on the 15th the patient was able to go out and attend to his business. (a)

(a) *Three cases of sudatoria, observed in the Hotel Dieu, during the summer, 1842.* The following cases of a very rare affection were reported, by M. Marrotte, as having appeared in Paris, towards the close of the epidemic of typhus fever which had raged in that city. M. Honoré, in whose wards the patients lay, had never before seen cases of this disease; and M. Rayer, who is well acquainted with the disorder, had never seen it in Paris.

"CASE 1.—A young man, twenty-three years of age, was received into the hospital, July 29, complaining of pain in his head, lassitude, great prostration, thirst, and drowsiness. His skin was hot, pulse frequent, tongue and teeth foul: had had no action of bowels, which could only be brought to move by medicine; no rumbling in the iliac fossa. There were none of the lenticular spots which accompanied the prevailing epidemic. The skin, though very hot, was neither dry nor burning; on the contrary, it was moist. He complained, moreover, of an uneasy sensation and feeling of anxiety at the pit of the stomach, which led to the administration of an aperient emetic.

"The present symptoms have lasted for three days. His first indications of disease were, general uneasiness and loss of appetite, which were not sufficiently pressing to induce him to relinquish his duties. Suddenly, in the middle of the day, he was seized with pain in the

head, and great prostration, which forced him to take to his bed, but he had no rigors, nor diarrhœa; his skin was at the same time covered with a moderate, though constant perspiration.

"For two or three days after admission, the patient continued in the state above described, without having been benefited by a bleeding from the arm, practised previously to his application at the hospital. After this period, the disease assumed all its severity; the prostration and drowsiness were more marked; the perspirations and oppression became more intense. The perspirations streamed forth continually from the skin, the heat of skin increased, the pulse became stronger and more frequent, the oppression was accompanied by cough and mucous expectoration, and auscultation discovered mucous râles throughout the whole extent of the bronchi.

"This combination of symptoms persisted in all their force for ten or twelve days: at the expiration of this period, the patient felt improved. His amendment seemed in some degree to have been effected by a change in the position of his bed to a better ventilated situation. Under the influence of this change of position, the perspirations diminished, the tongue became soft, moist, and simply furred; the teeth became clean, and the thirst was diminished.

"On the 25th of August, the patient is progressing; the surface is still moist in situations where the skin is naturally perspirable. Vesicles are dispersed about the neck and trunk, some being filled with a milky serum and surrounded by slight areola; others being transparent. The return of appetite is more tardy.

"CASE 2.—A man, upwards of six feet in height, thirty years of age, had felt every evening a sensation of feverishness for about twelve days; his appetite failed; he suffered from thirst; his skin felt burning hot, and he experienced considerable drowsiness. Since his admission, the fever has become increased and continued; his skin is covered by a constant perspiration; he has headache, pain in the left side, anxiety, and oppression at the præcordia.

"In the course of five or six days, the anxiety and oppression have assumed an excessive degree of intensity; he has cough and expectoration, and mucous râles are very obvious throughout the whole of his chest. The perspirations have increased, together with the heat of skin, and the hardness and frequency of the pulse. The abdomen is distended, the tongue thickly furred; there are great prostration, and perpetual drowsiness. An eruption of red pimples appeared upon the neck, and spread thence to the face and trunk; in two or three days these pimples were surmounted by vesicles, containing a lactescent fluid, and were followed by successive eruptions of sudamina, chiefly of the phlyctenoid kind, which occupied the vacant spaces between the papulæ.

"As the eruption increased and advanced in development, the oppression diminished, the pulse became softer, and the abdomen diminished in bulk. In this patient, as in the former, the bowels were inactive, and required the aid of medicine. His intellectual powers were unaffected, and the appetite returned gradually to its normal standard during recovery. On the 25th of August he was convalescent.

"CASE 3.—A young man, twenty-four years of age, for some time past suffering from uneasiness, loss of appetite, and lassitude, for which symptoms he was bled from the arm without benefit. He was next seized with headache, vomiting, diarrhœa, and perspirations, and was forced to take to his bed, where he remained for eight days, suffering with perspirations during the whole period.

"On admission, August 16th, he was in a state of extreme prostration; heaviness was exhibited in his features, his tongue and teeth were covered with sordes, the perspirations were general and continual, his abdomen was distended, and he suffered from thirst. For several days he remained in this state, answering with difficulty the questions that were put to him. He had retention of urine, and upon the passage of a catheter, a full basin of clear urine was withdrawn. In seven or eight days from this time, his state was improved; the stupor has diminished, and the tongue is moist. The perspirations are mitigated, and this mitigation became strikingly apparent as soon as the patient was removed to a better ventilated situation. They have not yet, however, wholly ceased; the hardness and frequency of the pulse have yielded.

"From this period, amelioration was as speedy as in the former

## SUDAMINA. (a)

Vocab. *Hydroa, Sudamina.*

385. *Sudamina* is a title given to minute prominent vesicles, the size of millet-seeds, of a round shape, transparent, and formed by a limpid watery fluid effused under various points of the epidermis. These small vesicles occur, without accompanying redness of the skin, in the course of many acute and chronic diseases, independently of the severity of their general symptoms.

386. *Causes and symptoms.*—This peculiar eruption is only observed in morbid states of the system. It appears most generally in dothineritis (*typhoid fever*), in scarlatina, measles, pleuro-pneumonia, and peritonitis, especially in that form of the disease which occurs during the puerperal state. I have observed it occurring, although very rarely, in diseases of no severity,—such as slight intermittent fevers and trifling affections of the mucous membrane of the bowels.

387. *Sudamina* almost always appear along with profuse sweating, but in the furuncular affection of the bowels (*dothineritis*) I have seen the eruption take place without any sensible increase of the cutaneous perspiration. On the other hand, I have occasionally witnessed very profuse perspirations without the evolution of *sudamina*; among the phthisical, and those affected with the sweating miliaria of 1821.

*Sudamina* more commonly appear in the course of acute or chronic diseases, among females than males, among the youthful than those of riper years, and less frequently among the latter than the aged. The eruption is more commonly met with during the hotter months; the colder seasons of the year, however, do not prevent its occurrence.

388. *Sudamina* may appear on almost every part of the body, but occur more generally on those regions where the cuticle is the thinnest and most delicate, as on the front of the abdomen and thorax, on the neck, groins, and axillæ. The eruption very seldom occurs on the skin of the back, limbs or face.

Occasionally the eruption is almost general; more frequently, however, it appears on only one, or but a small number of districts at the same time.

The eruption is never preceded by a sense of tingling in the parts it invades. The size of the vesicles is very variable; some are so small as to be barely perceptible to the naked eye, whilst others equal a millet-seed in size. The vesicles, which at first sight, might be taken for small drops of perspiration, are rounded, globular and prominent, and so brilliant and transparent that they seem deposited on the surface

cases, but the return of appetite was not so marked as is customary after typhus fever; he was not so much emaciated as are patients convalescent from the latter disease, but he appears more debilitated.

“M. Marotte remarks, with regard to these cases, on the exacerbation which took place at the close of the fifth or sixth day; the continuous perspirations which existed at that period both day and night; the intensity of the prostration and drowsiness; the cutaneous eruption which at this period made its appearance, but without being critical; the oppression and anxiety at the præcordia appearing with the perspirations; the protraction of amendment to the term of two weeks from invasion; the continuance of perspirations to the close of the third week, and the marked benefit resulting from better air and ventilation; all of which symptoms he looks upon as pathognomic.

“Contrasting the disease with typhus fever, he recalls the negative characters of sudatoria. There was no diarrhœa in the commencement; there were no headache, rigors, or vomitings; the prostration of the physical powers is rarely so great; it is rare that the tongue and teeth are so speedily covered with sordes, or that drowsiness is so strongly marked. The first week passed away without epistaxis, and without lenticular spots. The pulse of sudatoria, again, has never the smallness and frequency of the pulse of typhus.” Wilson (*op cit.*)

(a) M. Rayer very properly separates miliaria, or military fever, which is often a severe constitutional disease, and sometimes prevails epidemically, from *sudamina*, which is symptomatic and the occasional accompaniment of so many different diseases.

of the skin. Although most generally distinct, they are occasionally seen confluent, in which case they form small irregular bullæ, similar in their colour to that of the skin, around which no redness is perceived, except in a few extremely rare instances, and then it is only at the base of a very small number of the vesications.

In some cases the vesicles within a few hours after their appearance begin to fade and grow milky, when they quickly disappear. In others, again, they preserve their perfect transparency and globular form for four and twenty hours and even longer; they then lose their lustre, shrivel, and, before the end of the third or fourth day, are no longer to be seen. Lastly, it sometimes happens that this eruption runs its course more slowly, and does not totally vanish before the seventh or eighth day. The vesicles of *sudamina* rarely burst of themselves; the fluid they contain is usually reabsorbed; the epidermis is thrown off and no trace of their existence is left. Although ruptured by the rubbing of the clothes, as frequently happens, they never give rise to the formation of scabs. If they be opened a short time after they appear, a small smooth and reddish depression is perceived in their interior, which is effaced in the course of a few minutes. When the vesicles have been very numerous or confluent, the cuticle is occasionally detached in pieces of some magnitude. It even happens occasionally that the slightest friction is sufficient to detach it from the intervals of skin between the vesicles, thus exposing the naked surface of the corion, which is at first of a pale rosy-red hue, but speedily acquires a brighter tint.

When the eruption has disappeared spontaneously, small whitish spots are observed to remain, corresponding with the points occupied by the vesicles. These marks are speedily effaced.

The eruption of *sudamina* usually occurs successively; but it may show itself on several regions at the same time.

As to the fluid contained in the vesicles of *sudamina*, it is thin, (*vaporis instar*, Becker,) colourless, inodorous, almost tasteless and without viscosity; it does not redden turnsole paper, and appears therefore to differ from the perspiration, which has usually this property.

389. *Diagnosis.* It is enough to have seen the eruption of *sudamina* once to recognize it ever afterwards. The touch distinguishes it in an instant from drops of sweat standing on the surface. It is never preceded by redness of the skin, nor by pruritus, like eczema, hydrargyria, and the vesicles which follow exposure to the burning rays of the sun, (*eczema solare*), with which it has been, by mistake, confounded. The eruption of *sudamina* is not preceded, and still less is it accompanied by the febrile symptoms which are observed along with the sweating miliaria, and the other eruptive fevers. Nevertheless, puerperal peritonitis attended with an eruption of *sudamina* (which was improperly designated under the title of *miliary fever*) was long and is still occasionally confounded with the epidemic miliaris sudatoria or sweating disease of Picardy.

390. *Prognosis.*—*Sudamina*, and the sweating which accompanies the eruption, have appeared to be critical under certain circumstances. This eruption, however, in the great majority of instances, does not seem to have any influence on the progress of those diseases in the course of which it occurs; it is a phenomenon the more and nothing beyond.

Several writers have looked on the eruption of *sudamina* as an unfavourable symptom; and it is undeniable, that it happens more commonly in severe diseases than in those that are unattended with danger.

*Historical Notices of the Disease.*

391. Forestus<sup>1</sup> has specified the principal characters of *sudamina*; the definition of Blancardus<sup>2</sup> appears applicable to lichen and eczema solare. Under the title of *hydroa*, Jos. Frank<sup>3</sup> has comprised and described the lichen *tropicus*, herpes *labialis*, and the peculiar eruption of typhoid fevers: this is more than mere confusion of nomenclature.

M. Barbié du Bocage<sup>4</sup> has detailed an excellent account of the

characters of sudamina. Andral<sup>1</sup> has given a case in which the vesicles were as large as bullæ. M. Louis<sup>2</sup> has seen the eruption accompanying phthisis and dothineritis; I have, myself, met with it, I may say, in all the diseases during the course of which it is liable to occur; and if I give no particular instance of it here, it is because the eruption is, in fact, a symptom common to many maladies, and of no great importance in itself.

## ARTIFICIAL VESICULAR ERUPTIONS.

392. The following cases seem to me calculated to convey some information upon those artificial vesicular eruptions, the speciality of whose several causes characterizes them individually, and the short duration and slightness of which, separate them no less distinctly from the whole of the other eruptions that appear under the same elementary form.

CASE LIX.—*Vesicular and papular eruption produced by exposure to the sun's rays (eczema solare, Willan).* Mr. G. having, on the 20th of July, 1821, bathed in the Seine at mid-day, during excessively hot weather, got scorched with the sun. In the evening, the nape of the neck, the back, loins, shoulders, and inner parts of the arms, became of a scarlet-red, and continued extremely itchy during the whole of the night. Next morning an immense crop of vesicles could be distinguished by the naked eye, and still better by the magnifier, covering the red and inflamed surfaces of the skin. These vesicles were of the size of the head of the smallest pin that is made, and contained a small drop of transparent serum, the presence of which could be readily demonstrated by piercing them with a fine needle. Dispersed among these innumerable vesicles, there were a certain number of solid elevations similar to the papulæ of lichen, which contained no fluid. The eruption was not accompanied with fever, nor with any other derangement of the functions generally; (*cold-bath, sherbet of tartaric acid, antiphlogistic regimen.*) During the next and following day, there was a gradual abatement of the redness of skin, and the vesicles and papulæ were less distinct than they had been. The same plan of treatment was continued. Three days afterwards, a slight desquamation took place from the back, the pruritus ceased completely, and the patient felt perfectly recovered.<sup>3</sup>

CASE LX.—*Vesicles produced by exposure to the sun.* M. \* \* \*, thirty-two years of age, somewhat corpulent, and having a fine skin, after the excessive heat that was felt on the 10th and 11th of June, 1825, experienced a considerable degree of itching on the backs of the hands and between the fingers, occasioned by elevations, on the nature of which I was consulted. The skin in these places, which were rough to the touch, presented an immense quantity of minute vesicles, the greater number of the size of a pin's head, and a few a little larger. These vesicles were very irregularly scattered over the parts mentioned. The skin did not appear inflamed, except in those situations where the patient had scratched himself; and in these the vesicles were succeeded by small yellow scabs. The hands were swelled and red, as they usually appear during the heat of summer. I recommended M. to endure the pruritus without scratching, to bathe the hands frequently with cold water, and not to expose himself to the rays of the sun, but to wear light muslin gloves. The vesicles continued five or six days longer; the itchiness then diminished, and on the 23d of June, no traces remained of this slight inflammation. Small circular laminae of the epidermis were subsequently detached from several points which had been the seat of vesicles.<sup>3</sup>

CASE LXI.—*Artificial vesicles from the application of a Burgundy pitch-plaster.* Plasters of Burgundy pitch frequently excite a vesiculopustular inflammation, when they are kept applied for too long a time. M. D. \* \* \*, thirty-eight years of age, of a stout and plethoric habit, consulted me on account of a lumbago with which he had been affected several times. I recommended the use of purgative glysters,

and the application of a Burgundy pitch-plaster to the loins. Three days afterwards, M. D. \* \* \* summoned me to his assistance in order to free him from his plaster, which had caused so much itching that he had not closed his eyes during the preceding night. On removing the plaster, I perceived that the whole skin of the loins was covered with an infinity of small, transparent and but slightly prominent vesicles. The skin in this situation showed nothing of a general erythematous blush; it was only here and there it appeared a little redder than in the natural state. The inflamed skin was cleansed with a little oil, and covered with compresses dipped in the mucilaginous decoction of althæa and poppy-heads. Eight days afterwards the lumbago and vesicles were both completely cured.

CASE LXII.—*Eruption similar to the eczema rubrum from the internal use of cubebs pepper.* N. \* \* \*, thirty-eight years of age, contracted a clap in the month of March, 1829. After a due interval had elapsed, I commenced administering the cubebs pepper in the dose of a drachm every day. After four doses had been taken, the discharge was considerably diminished, and no longer accompanied with pain. After the sixth dose, N. \* \* \* felt the whole skin of his body become excessively itchy. This sensation was speedily followed by an eruption, the size of pin's heads, and not very prominent, which appeared principally about the instep, and over the wrists and knees, situations where the pruritus had been more particularly troublesome. The skin was hot, red and swelled. The eruption seemed to differ in nothing from that which characterizes *eczema rubrum*: vesicles were very distinct under the magnifier, and when pricked with a fine needle, a small drop of transparent serum escaped from their interior. The affection of the skin was neither attended with fever, nor with any other evident functional disturbance. Compresses wetted with soothing decoctions, applied to the affected parts, were found to increase the pruritus, and were consequently discontinued. Keeping the parts exposed, and sponging them repeatedly with cold water, gave speedy and great relief. The inflammation abated in the course of a day or two; a few of the vesicles became covered with small yellow scabs; in general, however, they were only followed by desquamation of the cuticle, the fluid they contained being in all probability reabsorbed. Within eight days the patient was well.

CASE LXIII.—*Vesicular and pustular eruption from the external application of the oil of the croton tiglium.* I. M. \* \* \*, aged sixty-four, was admitted into the hôpital de la Pitié, on the 29th of February, on account of a *gastro-enteritis*. With a view of relieving the constipation of the bowels, thirty-two drops of the croton oil were directed to be rubbed in upon the abdomen. This application was followed by alvine evacuations, and by a vesicular eruption of the skin, the cause of which was at first overlooked. On the morning of the 8th, the face of the patient looked puffed, and the skin of the forehead and cheeks was of a pale red colour, which disappeared on pressure. Towards the alæ of the nose and over the left cheek, a number of excessively minute whitish vesicles were discovered. 9th. Face swelled, and redder than ever; and the cheeks, lips, chin and nose, were now distinctly seen to be covered with small whitish vesicles, very much crowded together. These were prominent, and without areolæ. The eyelids were slightly œdematous. The skin of the abdomen was covered with a vast number of vesicles of the same form, but larger and more elevated. These were white, filled with a limpid serous fluid. An eruption of the same kind was observed on the forearms. 11th. Desquamation had taken place around the mouth and upon the lips; the redness and puffing of the face had disappeared. 12th. Desquamation going on over every part of the face and abdomen that had been affected. Termination of the eruption. The treatment of the affection of the digestive organs was continued.

## II. PUSTULÆ.

## PUSTULAR INFLAMMATIONS.

Vocab. Pimple, Pustule, Psudracia, Phlyzacia.

393. The pustular inflammations of the skin are characterized by the evolution of *pustules*; that is to say, by circumscribed pimples from half to three-quarters of a line in diameter, often surrounded at their base by an inflamed areola, and formed at their acme or height by a purulent, non-serous fluid, deposited within a follicle, or between the outer surface of the corion and the epidermic layers. Pustules terminate variously, by the *reabsorption* or the *desiccation* of their fluid contents, in the latter of which cases, scabs are formed by *ulceration*, and by *tuberculated induration*. Their presence is subsequently indicated by *marks*, and frequently by *cicatrices*.

394. Seven forms of pustular inflammation of the skin are reckoned; *variola* and its modifications (*varicellæ*); *vaccinia* and its modifications (*vaccinellæ*); *acne*; *rosacea*; *mentagra* or *sycosis*; *impetigo*; *favus*; and *ecthyma*. To these must be added artificial pustules, and pustular syphilis, which I have, however, seen reason to associate with a different order.

I have already observed, that in the arrangement of Bateman, scabies was erroneously placed among the pustular diseases, and I shall now give my motives for grouping together variola and the different varieties of *varicellæ*, three of which are decidedly pustular in their nature; *vaccinia* and the *vaccinellæ* I have also felt obliged to class with pustules and not with vesicles. Pustules, in fact, differ from vesicles, not only in the circumstance of their containing pus or a non-serous fluid at the period of their height, but farther by the depth and intensity of the inflammation attending them. The latter character has appeared to me of so much the more importance as the serum of almost all vesicles becomes turbid, and occasionally even purulent at the time of their desiccation, whilst the fluid contained in several pustules is unquestionably serous at the outset. Willan and Bateman are both evidently mistaken when they maintain that *rosacea* and *mentagra* begin by tuberculations, for these diseases are undoubtedly *pustular* at first. Of the *tineas* and *porrigos* I have only preserved *favus* (*porrigo lupinosa*, and *porrigo scutulata*), having for several years past, perceived that the other eruptions of the hairy scalp were mere varieties, owing to peculiarities in the structure of the surfaces affected, of *eczema*, *impetigo*, *psoriasis*, &c.

395. Viewing pustules in a general manner, Willan conceived that they might be reduced to two principal forms. And we do, indeed, observe that some are usually of a large size, seated on an indurated circular and inflamed base, and terminate in a hard thick scab, generally of a brown or brownish colour: such are the pustules of *variola*, of *ecthyma* and of *vaccinia*. These are the *phlyzacious pustules* of Willan. Others, again, the *psudracious pustules* of the same author, are small in size, often irregularly circumscribed, scattered or arranged in clusters, and terminate in crusts of various forms (the pustules of *impetigo*), or by tuberculated indurations (the pustules of *rosacea*, *acne* and *sycosis*); but these various species of pustules present other differences in their modes of development, and in their appearances, which render this distinction of Willan altogether of secondary importance.

396. Among the pustular inflammations some, as *acne*, *rosacea* and *mentagra*, are partial, that is to say, they never appear over the whole surface of the body; others, such as *variola*, *favus* and *ecthyma*, either appear on or may extend to every region of the skin.

Pustular diseases are occasionally accompanied by inflammatory affections of the mucous membranes. But the variolous eruptions are the only ones in which these membranes actually exhibit in those places where they are provided with an epithelium, true pustules analogous to those which are perceived on the skin.

397. Each pustular inflammation possesses peculiar characters which are due to its seat, its form, its extent, the amount of inflammation accompanying the pustules, and the mode of their eruption,

as this is simultaneous or successive. Some pustules, as those of *rosacea*, are flattened; others, as those of small-pox, are acuminate in their commencement and umbilicated or depressed in their centre at the acme of their development, and so forth. The fluid which pustules contain, usually opaque and white at their height, is transparent and viscid at first in *vaccinia*, and pasty in *variola*. This fluid is generally deposited in a single cavity; in *vaccinia*, however, it is included in a multitude of cells. The matter of the pustules of *variola*, *vaccinia* and *favus* is contagious.

398. The greater number of pustules dry off in the form of *scabs* (*impetigo*, *variola*, *vaccinia*, &c.); some of them decline at times into true *ulcers*, (*ecthyma luridum* and the pustules of syphilitic origin); and others frequently degenerate into *tubercles* (*acne*, *rosacea*, *mentagra*).

The scabs produced by the drying up of pustules, present secondary characters, which demand attention. Those of *favus* are yellow and cup-shaped; those of *impetigo* are prominent, yellowish, greenish or brownish in colour (*impetigo figurata*), and granular (*impetigo of the scalp*), or stalactitic in form. The characters supplied by the chemical analysis of scabs are of but little interest; and as scabs and incrustations are only formed during the latter stages of pustular inflammations, it is easy to conceive that distinctions based upon such grounds must be extremely vague and imperfect.

The state of the skin beneath scabs, ought to be so much the more carefully investigated in the diverse species of pustular inflammations, as the incrustations may be accidentally altered, having been removed entirely, or in part, by washes, cataplasms, and other topical applications. The measure and amount of these hidden alterations of the skin, the number, the form and the appearance of the *erythematous patches*, of the *sores*, and of the *tuberculations* which follow pustular inflammations, ought to be studied and detailed with the most scrupulous precision. Even the *cicatrices*, when they occur, are occasionally found to be stamps characteristic of the disease which has produced them.

399. The greater number of the pustular inflammations may, upon occasion, be observed occurring at the same time, and complicating one another, without their respective courses being in any way influenced by this circumstance. Others, on the contrary, such as small-pox and cow-pock, are never developed simultaneously without being modified; they are even mutually exclusive of each other in the majority of cases in which one of them has gone regularly through its several stages. Pustular inflammations are also occasionally complicated with cutaneous affections of a different order. Lastly, pustular eruptions are frequently preceded or attended by inflammation in a greater or less degree of the mucous membranes; and those of *variola* especially, and at times even of *varicella* and *vaccinia*, are ushered in by other functional derangements of various degrees of severity.

400. The duration of the pustular inflammation is extremely various; some of them, as *variola*, *varicella* and *vaccinia*, are regularly *acute* and rapid in their course; *favus*, *rosacea*, *mentagra*, &c., are as constantly chronic in their nature.

401. Of all the different forms of cutaneous inflammation, vesicles are the most nearly allied to pustules. The latter differ from the former by being evidently accompanied with a higher degree of inflammation, and more frequently followed by *cicatrices* and tuberculated indurations. Pustules, at their *height*, are easily distinguishable from the *exanthematous*, *papular*, *tubercular*, *squamous* and other forms of inflammation; but this is not the case at every period of their development; and in some cases it would even be impossible to say, from a simple inspection of the eruption, and without taking into account preceding symptoms, the rapidity or tardiness of its evolution and so forth, whether the disease was to be pustular or not in its future stages. The *spots* or small *red elevations* by which the greater number of pustular diseases are announced are not characteristic; pustules in themselves are in fact only completely proclaimed at the summum of their development; several, as those of *vaccinia* and of *varicella*, begin by small papular elevations of the skin, the summits of which are soon filled with a limpid fluid like that of vesicles, and only ultimately acquire the character of pustules. Lastly, the scabs, *erythematous spots*, *ulcers*, and *indurations* that succeed pustules, have not regularly and in every species, external characters

<sup>1</sup> Levain. Essai sur l'eczema, p. 19, 4to. Paris, 1830.

sufficiently striking to admit of a diagnosis being established after their mere appearances. (a)

(a) Mr. Wilson includes some of the *pustulæ* of Willan. M. Rayer under the head of *Suppurative inflammation of the Dermis*. His introductory remarks on the occasion come in appropriately in this place.

"Under the influence of a degree of inflammation of the dermis, for the most part greater, at least at its commencement, than that which exists in the effusive group of diseases, the inflamed dermis gives rise to the formation of pus; the pus occupying the surface of the dermis, and producing an elevation of the epidermis to a limited extent. This irregularity of the surface of the skin—namely, an elevation of the epidermis consequent on the presence of pus, is termed a *pustule*, and this is the only accurate sense in which that term can be employed. There is a wide distinction between a vesicle and a pustule, when these two pathological forms present their typical characters; but it not unfrequently happens, that in consequence of a reparative action set up in the vesicle, pus is produced upon its dermic base, and mingling with the serum, constitutes a sero-purulent, and subsequently, a purulent or pustular vesicle. In such a case it is necessary to remember that a true pustule contains pus from the first moment of its formation, and by this circumstance is essentially distinguished from a vesicle.

"It is requisite, at the outset of our study of cutaneous diseases, to be most precise in our definitions, and to draw as broad a line as possible between the various pathological forms which we are desirous of characterizing. Scarcely any word has been used more loosely than the term pustule in medical nomenclature. At one time it was employed to signify a papula, at another a vesicle, and it was not until the time of the Linnæus of cutaneous pathology, that the proper application of the term was truly made. Willan employed it, with the characters above stated, as the type of his fifth order—*pustulæ*; and in this sense it has been subsequently adopted by successive dermatologists.

"The diseases which I propose to consider under the definition above given, are two in number—namely,  
Impetigo,  
Ecthyma.

"The order *pustulæ* of Willan embraces five diseases, two of which, had he lived at the present time, would, I am convinced, have been excluded by himself—namely, porrigo and scabies. The genus porrigo of Willan contains diseases of the most opposite kind, and has been the source of much confusion, so much, indeed, that it would be well that the term should, for the future, become obsolete and forgotten. What relates to true porrigo will be found in this classification under the designation, *favus*. Scabies, again, is a disease possessing several elementary forms, of which both vesicles and pustules are accidental, and only occasionally present; the pustules, when they exist, belonging to ecthyma. Variola, as placed by Willan in the order *pustulæ*, is forcibly torn from all its natural affinities, and for this reason I have thought it correct to transfer the genus to the group of eruptive fevers. Rayer admits no less than ten genera of pustular inflammations, for four of which he is indebted to variola—namely, variola, varicella, vaccinia, and vaccinella. There could have been no objection to thus establishing a distinct group of variolous affections—indeed, some benefit might have flowed from such an arrangement—but the possible advantages are immediately destroyed by the companionship with which he has leagued them. Thus, from the highly inflammatory and contagious fever of variola, we pass on immediately to three diseases of the sebaceous glands—namely, rosacea, acne, and sycosis; next in order follows impetigo, then favus, a peculiar disease of the hair follicles, and lastly, ecthyma.

"The genera impetigo and ecthyma constitute the two essential forms of pustules indicated by Willan—namely, *psyrdracia* and *phlyzacia*, the former being a *psyrdracious* (ψυδρα, ψδραξια, frigida guttula) pustule—that is, 'a small pustule, often irregularly circumscribed, producing but a slight elevation of the cuticle, and terminating in a laminated scab. Many of the *psyrdracia* usually appear together, and become confluent; and, after the discharge of pus, they pour out a thin, watery humour, which frequently forms an irregular incrusta-

Vocab. *Variola, Varioloid, Varicella, Small-pox, Chicken-pox, &c.*

402. Under the name of *variolous eruptions*, I comprise several vesiculo-pustular, acute and contagious inflammations of the skin, which the strong resemblance they bear to each other in their mode of development, in their course, and especially in their constant association, when small-pox appears as an epidemic, as well as their reproduction mutually, the one by the other, authorize us in considering as effects of one and the same cause.

These eruptions have, in truth, a greater number of points of resemblance and of natural connection than many other diseases, the identity of whose origin has never been disputed,—than syphilitic affections for instance.

403. The variolous eruptions may be arranged under two series: the one comprising the *pure and legitimate variolæ* which give the type to the genus; the other including the *varicellæ* which appear to be modifications of the former. This second series may be subdivided into five principal forms, most usually met with mingled together; these are:—

- 1st. The *pustular umbilicated varicella* or varioloid;
- 2d. The *pustular conoidal varicella*;
- 3d. The *pustular globose varicella*;
- 4th. The *papular varicella*; and
- 5th. The *vesicula varicella* or chicken-pox.

404. The affinity of these affections, or their origin from the same source, is demonstrated by the following facts:

1. During the prevalence of a variolous epidemic those individuals who have never had either small-pox or cow-pox, are almost inevitably attacked with the pure or legitimate variola, characterized by an eruption of umbilicated pustules and the occurrence of secondary fever; other individuals again, and these are such as have either had small-pox naturally or by inoculation, or such as have been vaccinated, show the umbilicated pustules of variola, but at the end of the seventh or eighth day there neither occurs any period of suppuration nor any secondary fever (varioloid); in some others, independently of this change in the current and duration of the disease, the form and structure of the pustules are modified (pustular conoidal, and globose varicella); in others still, the appearance of the eruption is even farther changed, and instead of pustules we have papulæ and true vesicles thrown out on the skin (papular and vesicular varicella or chicken-pox); lastly, in a very small number the disease is proclaimed by the same general symptoms, and advances without any eruption (variolous fever). This manifestation, or rather this association of variola and of the varioloid and other varicellar eruptions, during the prevalence of a variolous epidemic, was particularly observed in Scotland in 1818; in England in 1822–23–24 and 25; at Philadelphia in 1824; at Montpellier in 1819; at Paris in 1825; at Marseilles in 1828, and in many other places.

In the epidemic of Paris, in 1824, variola prevailed during July and August, and varioloid and varicella during September. In the attack of 1825, cases of varioloid and varicella were observed during the whole continuance of the epidemic, but were more particularly abundant in the month of October when its virulence had abated. One single cause, the epidemic influence, gave occasion to these various eruptions; they were observed in the same districts, the same streets, the same houses; if the disease broke out in a large family,

tion.' The latter, a phlyzacious (φλυξεν, to be hot) pustule—that is, one, 'commonly of a large size, raised on a hard circular base, of a vivid red colour, and succeeded by a thick, hard, dark-coloured scab.' The achor and the favus of Willan are no longer considered as pustules.

"The transition, which I have already had occasion to remark, from erythema to pemphigus, and from rupia to herpes, may also be extended to pustulous affections. Eczema, in certain of its forms—as in the impetiginous variety—is seen gradually merging into impetigo, while ecthyma is farthest removed, both in position and characters, from the vesicular group."

one was attacked with variola, others with varioloid, and others with vesicular varicella.

2. A varicellar epidemic is never observed to occur without cases of variola and of varioloid; nor a variolous epidemic ever to prevail without cases of varioloid and varicella making their appearance; all are effects of the same medical constitution. As to the relative proportion of the different species of eruption, it would be difficult to come to any precise conclusion at present. The French practitioners at first, only recognized two species of variolous eruption—variola and varicella; whilst in England, two varieties of varicella—chicken-pox and swine-pox, and subsequently several others, as horn-pox, hives, &c., were described. Odier and other observers, without fixing the precise number, have admitted several kinds of varicella; others, Lavit and Berard in particular, have regarded these diseases as anomalous variola; lastly, it is only of late that another variety of varicella, more akin to legitimate variola, than any other eruption,—the varioloid, has been accurately described. Although, then, the proportions of these different species of eruption cannot be estimated in any even of the more recent variolous epidemics, their association, and their development under the influence of the same cause, are not the less incontestable.

3. Variolous epidemics are occasionally varicellar at their beginning and termination, and truly variolous between these periods.

4. In a single individual attacked with true variola, we occasionally perceive the whole of the varieties of form and appearance which are ever presented by the variolous eruption, to wit: umbilicated, globular, and conoidal pustules, papular rashes, and vesicles.

5. The inoculation of variolous matter has occasionally given rise to the evolution of varicella,<sup>1</sup> that is to say, to an eruption, the natural cure of which took place on the eighth or ninth day, without secondary fever.

6. As to vesicular, varicella, or chicken-pox, the truly variolous nature of which has been most keenly contested, Dr. Thomson has demonstrated from facts, on the one hand, that healthy persons brought into contact with individuals labouring under this form of disease, have caught the true small-pox; and, on the other, that exposure to the contagion of variola, has given occasion to the development of chicken-pox.

7. With regard to the symptoms in variola, varioloid and the other varicellæ, the analogy is complete in every particular, during the periods of the incubation and of the development of the eruption. And we see, in fact, that if the pustules of a variolous eruption begin to dry up from the fifth to the sixth day, the greater number of practitioners will style the disease *varicella*; if they do not begin to decline before the seventh or eighth day, the disease will be pronounced a *varioloid*; and if they continue in a suppurating state for some days longer, the disease will be entitled *variola*; the principal difference evidently lies in the longer or shorter duration of the disease. But this is no essential difference; for we see that confluent variola, distinct variola, and inoculated variola, have not all the same course, nor especially the same periods, and yet they are very certainly of the same nature, seeing that they readily spring the one from the other.

8. To conclude, variola or true small-pox, the varioloid or modified small-pox, and the varicellar eruptions—chicken-pox, horn-pox, &c., are the varied effects of the same cause; for under certain conditions they may all be seen arising the one from the other.<sup>2</sup>

405. Nevertheless, many writers insist on separating several of these eruptions from variola. They support their views by statements and facts, of which I shall give a summary.

1. During the prevalence of a variolous epidemic, it is extremely difficult to ascertain precisely whether the development of this affec-

tion in an individual brought into contact with another labouring under varicella, be the effect of the communication, rather than of the epidemic influence which then engenders the disease on every side.

2. Vesicular varicella is not transmissible by inoculation, and is never observed giving rise to variola.

3. Those who believe varicella to be contagious, have confounded this affection with the varioloid, or modified variola.

4. Varicella occurs among those who have never been vaccinated, and who have never had small-pox; it cannot consequently be viewed as a variola modified by the previous existence either of this disease or of cow-pox.

5. Vaccination practised a short time after the disappearance of varicella, runs its course in the most regular manner; a circumstance which never happens when vaccination is performed after small-pox.

6. Variola often prevails epidemically, without being accompanied by varicella; and, on the contrary, this last affection may reign as an epidemic without being attended with small-pox. Thus, between 1810 and 1823, no cases of small-pox were observed at Copenhagen, and yet Dr. Moehl<sup>3</sup> informs us, that varicella appeared there almost every season.

7. Lastly, the characters of the eruption, and the symptoms of varicella differ essentially from those of variola.

406. I shall discuss these objections one by one.

1. It is not only during the epidemic prevalence of a variolous disease, that varicella or chicken-pox has been observed to give rise to variola; but under other circumstances which render the fact more conclusive and altogether without reply: "no case of small-pox had occurred in this town (Kirriemuir) for nine years, till last winter; when an idle boy, who was in the habit of wandering about the country, happened to be at a house where some of the inmates were said to be ill of the small-pox. He himself had been vaccinated some few years before. On his return home he was seized with febrile symptoms, and confined two or three days to his bed, when an eruption similar to chicken-pox, made its appearance. Immediately the fever abated, and in a few days more he left his bed and attended a cattle market, half a mile distant from the town, without any bad consequences. About a week afterwards one of his master's children was taken ill, and went through the regular stages of small-pox in a mild manner; then a second, similarly; a third suffered in a very alarming degree from the confluent kind; a fourth worse than the two first, and the youngest, of eight months old, had what, if the other cases had not occurred, I should without hesitation have called chicken-pox, for there was little or no fever, the pustules were filled with a watery fluid, which was not converted into the purulent appearance of small-pox. None of these children had undergone vaccination."<sup>4</sup>

2. The second objection is not better founded: several experiments prove incontestably that chicken-pox may be transmitted by inoculation.<sup>5</sup> It is true, indeed, that the inoculation of the matter of the

<sup>3</sup> De varioloidibus et varicellis, 8vo. Hafn., 1827.—Bullet. des sc. med. de Feruss. t. xiii. p. 47.

<sup>4</sup> Letter of Mr. John Malloch, Surgeon, to Dr. John Thomson, in his account of the varioloid epidemic, 8vo. Lond. 1820.

<sup>5</sup> The results of the experiments made up to the present time, upon the inoculation of the varicellæ may be arranged under three heads:—

1. The first includes those cases in which the inoculation was without effect, and these are the most numerous. Brasdor in reference to two children (Anc. Journ. de médecine, t. xlix. p. 308). Freteau, also in reference to two children (Journ. de méd. et de chir. par Corvisart, &c., t. ii. 1801). Thourer experiments on five children (Journ. gén. de médecine, t. xi. p. 132). Valentin (Journ. de médec. t. xiii.) The vaccine committee of France, in its report for the years 1806 and 1807; Bremer (Horn's archiv. für med. Erfahrung, 1801, p. 307); Chaussier, in report of vaccine committee of France, for 1813; Fontanelles in his descrip. de la vaccine qui a régné épidémiquement à Milhau en 1817, Montp. 1818, p. 39; Bryce, thirteen children inoculated who had no eruption, in Thomson's account of the varioloid epidemic, 8vo. Lond. 1820, p. 73; fourteen experiments without results, by Bartlett (in Edin. Med. and Surg. Journ. Oct. 1818); seven similar experiments by McIntosh, in Thomson, op. cit. p. 221; Carmichael, in Thomson's hist. sketch of the small-pox, 8vo. Lond. 1822, p. 277; Jackson (in Lond. Med. Rep. xv. p. 21); Heim (in Horn's archiv., Jan., 1825); Hesse, from whom these results are borrowed, thirteen fruitless experiments (in Allgem. med. annalen des xix. Jahrhunderts, June, 1828, p. 721).

2. The second comprises those cases in which inoculation was followed by a local eruption; cases of this description have been recorded by Willan (on vaccination, 4to., Lond. 1806); by M. Fontanelles (op. cit.) in two children; by McIntosh (in Thomson's acct., &c., cit. p. 113), on two children; and three cases are reported by Hesse (loc. cit.)

<sup>1</sup> Mr. W. Maxwell has reported that by inoculating with the virus of variola, he procured very slight eruptions without fever, which completely dried off on the eighth day, leaving no cicatrices.—Exp. on variolous inoculation, Edin. Med. and Surg. Journ., vol. xxii. p. 9. Dezoteux and Valentin also describe an inoculated variola, entitled by them the *brief species*, the duration of which is precisely the same as that of the varicellæ. Traité de l'inoculation, p. 223, 8vo. Paris, an. viii.

<sup>2</sup> I shall, by and by, have occasion to quote a remarkable fact in support of this assertion; others may most probably be found in a dissertation of Reil, and in a work of Stoll, copies of which I have not been able to procure. Reil. Diss. variolarum spuriarum ex verarum pure ortus. Halæ, 1792.—Stoll. Versuch einer medicinischen Beobachtungskunst (variola spuria veram producentes).

chicken-pox never communicates variola; but this circumstance does not annul the preceding fact, in which the inoculation is performed in another way; besides, the serous fluid of the pustules of variola not yet arrived at their height, when inoculated, does not always communicate small-pox, and this fact does not destroy their truly variolous nature, which even at this period is incontestable. Moreover, is it demonstrated that the fluids of the conoidal and globular pustules, or of the vesicles which are observed on some parts of the surface of almost every individual labouring under small-pox, communicate or transmit this disease with the same energy as the matter of the umbilicated pustules?

3. To say that those who consider vesicular varicella or chicken-pox to be contagious, have mistaken this disease for the varioloid, is to dispute the contagious nature of the chicken-pox, a fact experimentally proved, and gratuitously to suppose a serious error in diagnosis.

4. If varicella appear in persons who have never been vaccinated, this fact is not more extraordinary than that of the well-attested development of the varioloid, the variolous nature of which is not disputed, among individuals who have neither been vaccinated nor inoculated, nor had the natural small-pox.

5. Vaccination performed after chicken-pox, is undoubtedly most generally followed by regular cow-pox; but is it well ascertained that those who have had chicken-pox contract cow-pox and small-pox as readily as those who have never had this disease? During a variolous epidemic, individuals attacked with varicella rarely catch the small-pox; what is the reason of this?

On the other hand, it is incorrect to say that vaccination can never be developed in an individual who has had small-pox or varioloid.

6. What inference can be drawn from the fact of the course of varicella being always the same, whether the disease happen before or after the small-pox? Is not the course of the inoculated varioloid, or of the varioloid contracted by an individual during a variolous epidemic who has neither had small-pox nor cow-pox, the same as that of the varioloids observed among the vaccinated?

7. I deny, for my part, positively, that variola often prevails epidemically without being accompanied by varicella. As to those varicellar epidemics, independent of the cause of variola or of varioloid, which are admitted by Eichhorn<sup>1</sup> and several other authors, I do not remember to have met with a single well-attested instance of such an occurrence; the whole that are upon record have been observed during the prevalence of variolous medical constitutions.<sup>2</sup>

During the varicellar epidemic which prevailed in the Norwegian bailiwick of Smaalennen, in 1819, Dr. Holst<sup>3</sup> observed that the disease occurred both among those who had had small-pox and who had been vaccinated; about the same period a variolous epidemic broke out in the country around Christiana; in the epidemic of Milhau,<sup>4</sup> variola prevailed conjointly with varicella, and this connection has been ascertained to subsist in a very great number of variolous epidemics.

8. To say that the symptoms of varicella are essentially different from those of variola is absurd, inasmuch as the same eruption in a multitude of cases<sup>5</sup> has been considered as *varicellar* by some, and as *variolous* by others.

3. The inoculation of varicella lymph, has produced a general eruption in those cases related by Dimsdale (on inoculation, *Samml. auserles. Abhand. Bd. vii.*) by Mumsen (*Acta Hafniensia*, vol. iii. p. 33); by Heim (*loc. cit.*, and in Horri's archiv., Jan. and Feb., 1825); by Salmon and Willan, in the work of the latter on vaccination; by Fontaneilles (*descript. de la varicelle qui a régné épidémiquement à Milhau*, 8vo. Montpel., 1818, p. 81); by Dr. Thomson (*an acct., &c.*, p. 113); by Carmichael (*loc. cit.*) and by Hesse, in a case which he details in the publication already mentioned.

<sup>1</sup> Eichhorn (H.). Ueber die Behand. und verhütung der contagioes fieberhaften Exantheme, 8vo. Berl. 1831, p. 437.

<sup>2</sup> Thus in the varicellar epidemic of Copenhagen, described by Moehl, if no cases of variola were seen, many of varioloid were encountered. The varicellar epidemic, whose history is related by Mr. Barnes, was preceded several months by legitimate variola; and it is not shown that cases of varioloid were not observed at the same time with chicken-pox (see vesicular varicella).

Epid. varioleuse et pseudo-varioleuse (*Arch. génér. de médec.*, t. vii. p. 602).—Black (James). Obs. on small-pox, natural and modified, as they appeared at Newton-Stewart. (*Edinb. Medic. and Surg. Journ.*, vol. xv. p. 37.)

<sup>5</sup> M. Bousquet has given several instances in his *Traité de la vaccine et des erupt. varioleuses et varioliformes*, 8vo. Paris, 1833.

To sum up, then, none of the objections to the theory according to which variola and varicella depend on the same cause, appear to me of any weight; none of them cast a doubt upon the fact of the common origin of variola and varicella under the same epidemic influence, and especially that of the mutual and reciprocal development, in certain circumstances, of the one by the contagion of the other.

## VARIOLA.

Vocab. *Small-pox, Variola.*

407. Variola is an acute contagious inflammatory disease, proclaimed on the external surface of the body, in the course of the third or fourth day from the invasion, by an acuminated eruption, which arrives at its height between the seventh and eighth day, having in the mean time become pustular and umbilicated or depressed in the centre; the pustules after this still continue in a state of suppuration during a secondary fever of several days' duration; they then dry up and become covered with scabs, which finally, falling off towards the end of the third, and occasionally of the fourth week, leave small, irregular, and generally permanent cicatrices on the skin.

There are two very distinct varieties or kinds of small-pox: the one is known under the name of the *natural* small-pox, the other is the *inoculated* small-pox.

408. The *natural* small-pox presents four well-marked periods: that of *incubation*, that of *invasion*, that of the *eruption*, and that of the *desiccation*. In one instance the pustules are exceedingly numerous, agglomerated as it were, and united by their corresponding edges (*confluent small-pox*); at another the pustules are fewer in number, and are distinct or scattered singly over the whole surface of the body (*distinct or discreet small-pox*).

409. *Symptoms.*—First period.—*Incubation.* During the course of this period, which usually lasts from ten to twenty days, no morbid symptoms, either of a general or local nature, are commonly observed.

Second period.—*Invasion.* The attack of small-pox is always accompanied by symptoms of a more or less serious character. It is frequently marked by shivering fits which recur irregularly, by a subsequent rise of temperature, with dryness of the skin, or a disposition to sweating; there are acceleration of pulse, lassitude, pains in the limbs, back, loins and epigastrium; nausea and vomiting are common; the patient complains of violent pain in the head; he feels sunk to the earth, and is drowsy and restless. Among children, a state of somnolence is very common, and then they awake frequently with a start; or they are restless and toss about without shutting an eye, moaning pitifully. In some cases the face is flushed, and the patient might be believed on the eve of some cerebral affection, especially when the vomiting is troublesome, and the epigastric region continues free from pain on pressure, a suspicion which seems at times to gain in likelihood by the agitation of the patient and the convulsive twitches which often take place in the lips, the muscles of the face, or those of the body at large. To form a true estimate of these preliminary symptoms, it is necessary to keep in mind the prevalent constitution and reigning epidemic.

At other times, but less commonly, the patient yawns continually, complains of an indescribable sense of uneasiness, of dyspnoea, and anxiety; the beat of the heart is tumultuous and rapid; shooting pains are felt in the chest, which occasionally become fixed in a particular point, and symptoms of pleurisy appear to be present; or the patient is attacked with cough; or this symptom, in case it exist already, becomes more troublesome and incessant.

In some cases the nausea is incessant, the vomiting frequent, the thirst great, the tongue red upon its tip and edges; the abdomen, painful in different parts, most usually at the epigastrium, may be tumid and generally sensible to pressure, in which case we have often cerebral symptoms, a state of stupor, great prostration of strength, &c.

These various symptoms most usually occur independently of any local and primary lesion; they often appear simultaneously, as if all the systems of the economy were affected together.

In some bad cases the skin and origins of the mucous membranes present diffused ecchymoses or circumscribed livid spots before the appearance of the eruption (*variola nigræ*). Passive hemorrhages then frequently occur by the different natural passages, and are occasionally so general that the blood transudes by almost every abraded point of the body,—from the surface of blisters, for example, and from the bites of leeches, when any happen to have been applied.

These various phenomena, in sum, which appear before the eruption, may be combined in so many different ways, and run so completely into each other, that it is often difficult to distinguish upon which of the organs or systems the variolous virus has acted with the greatest intensity.

These properly precursory symptoms may cease with the appearance of the eruption, or continue during the whole course of the disease to its decline. It may even happen that a severe febrile paroxysm, accompanied with continual delirium and extreme restlessness, may cut off a patient in the course of a few days, whether the eruption have made its appearance or not. These initiatory symptoms most generally cease or abate when the eruption appears and is regularly developed; if they continue, they indicate the danger, already imminent, to be still greater.

Third period.—The eruption is speedily accomplished, especially when it appears after the occurrence of hemorrhage. From the second to the third day of the invasion, small and papular-looking spots which rise above the level of the skin, make their appearance. On the face they are commonly very numerous, and either greatly crowded together, or united by their bases and arranged in clusters (*variola coherentes*; *variola corymbosæ*). These have all a slightly livid tinge.

The eruption is occasionally preceded by a very extensive erythematous efflorescence of the face or trunk; in this case it is always confluent. The pustules show themselves on every part of the body,—in the mouth, pharynx, larynx, &c., as well as over the integuments. The face and neck swell in the same manner as in erysipelas; the patient complains of violent pain in the throat, and deglutition is performed with difficulty. Many white points, isolated or crowded together, appear on the membrane of the mouth, which is red and injected. The cough, which was hoarse at first, becomes dry, hard, painful and tearing; the voice, which was also hoarse at first, grows weaker and weaker, and is at length entirely lost. The restlessness and sense of anxiety continue, but there are not such marked symptoms of dyspnoea as in croup, which is further distinguished by a laryngo-tracheal whistling sound, not heard in small-pox.

At other times the eruption, having been preceded by symptoms of little severity, is evolved without any untoward accident; and it is in the passage from the second to the third period, that gastrointestinal affections, and especially a true dysentery (*variola dysenterica*, Sydenham), or, otherwise, variolous bronchitis, pleurisy, pneumonia, &c., are apt to intervene and cloud the prospect of a happy termination to the disease. Pneumonia occurring under such circumstances is, in one case, proclaimed by characteristic and decided symptoms; in another, and more dangerous instance, it is completely masked, and then it has often disorganized the lung by its progress, before even its existence is suspected. In the greater number of cases pneumonia interferes with the due development of the cutaneous eruption, and this complication is one of the most frequent causes of those irregular variolas which usually prove fatal, and which, by the older writers, were characterized as cases of *malignant* small-pox,—cases in which the evolution of the pustules was suspended, in which they became flaccid, and were mingled with sanguinolent bullæ, and in which the suppurating stage was slow of setting in.

Fourth period.—*Suppuration*. (Seventh or eighth day of the eruption.) An interval of four or five days divides the period of eruption from that of suppuration. During this time the small red papular spots of small-pox increase in size, and soon present a sort of flattening of their summits, followed by a central depression, by which each pustule assumes an umbilicated appearance. If the structure of the pustules be studied at this period, they are found to contain a little serum and a small disc of a whitish substance, which is very soft at first, but soon increases in consistency. On the third day of the eruption the central depression is very conspicuous in the greater number

of the pustules; their umbilicated aspect becomes more and more marked as they increase in size, and as the period of suppuration approaches; they are whitish in colour, and are surrounded by an areola of a red, or purplish red colour. When the pustules are confluent, or are clustered together in patches, these middle depressions are rarely perceived; from the second or third day the face then appears covered with a continuous sub-epidermic whitish pellicle,—a kind of membranous exudation, similar to that which is observed at the bottom of isolated pustules.

It is at this stage that the fever runs highest, and the most serious complications are observed to occur. The integuments generally appear swollen; those of the face, where the puffing is always considerable, are more especially affected. Delirium, or a drowsiness more or less oppressive, is occasionally observed. The vomiting may be obstinate, and attended with severe pain of the epigastrium; diarrhoea makes its appearance or increases. The character of the cough shows that the eruption has implicated the mucous membrane of the air-passages. A pyalism, whether there have been pustules on the mucous membrane of the mouth or not, now sets in and commonly becomes profuse. This symptom, indeed, often appears before this period, most usually showing itself between the third and seventh day of the eruption, at the same time as the swelling of the face, along with which it also declines. The pyalism may be accompanied by some difficulty of swallowing; it is a symptom which does not occur among children.

The number of pustules frequently bears no proportion to the excessive swelling of the face. The tumefaction often extends to the subcutaneous cellular substance to the neck and cranium. At this period the pustules look turgid with pus and centrally depressed on the trunk and limbs, where they are less numerous than on the face, except in those cases in which they become confluent on the inner sides of the thighs and on the buttocks, an event that is more particularly apt to befall young children, in whom these parts are habitually wet and irritable from the contact of the urine. Upon the parts just mentioned the pustules usually run their course more rapidly than elsewhere.

The presence of pustules upon the eyelids causes great irritation and very violent pain; those that are evolved on the mucous membrane of the mouth advance rapidly; in the larynx they are more tardy in their progress. In proportion as the pus is secreted, the pustules lose their flattened appearance and central depressions, and become more rounded and globular. When they are at no great distance from each other, the intervening spaces are red and swollen, and the patient complains of an extremely painful feeling of tension in the skin.

When the disagreeable symptoms which are often observed during the first stage, occur in this, the pustules rarely suppurate freely; the pustules are flaccid, and their areolæ look pale; or otherwise they become filled with a bloody serum and assume a livid hue; petechiæ appear in the spaces between them, large flaccid and bluish phlyctenæ are evolved (*variola confluentes crystallina*, Burserius), and passive hemorrhages takes place.

Fifth period.—*Desiccation*. This process almost always begins in the face; this part, indeed, is often completely covered with scabs, before the pustules on the lower extremities have attained their full maturity. The swelling now subsides, the pustules dry up, and the scabs that follow seem but to form one continuous incrustation over the face. The features are then hidden beneath a thick, brown-coloured mask, which falls off on the fifth or sixth day from the date of its formation, and is succeeded by a furfuraceous desquamation, the scales of which are several times renewed. The scabs in very confluent cases remain soft and moist. The patients exhale a peculiar faint and sickly smell; they complain of pain and tension in the integuments till the crusts are detached, an event that happens between the fifteenth and twentieth day from the attack of the disease. The pustules frequently ulcerate; their surface bleeds and becomes covered with black scabs. When these sores spread superficially and extend to the whole thickness of the corion, they are always followed by unseemly cicatrices in the event of the patient's recovery. At the same time the linen of the patient and the furniture of the bed are more or less soiled by the exudation of purulent matter from different parts of his body.

A pruritus of some intensity accompanies the formation of the scabs, and often induces patients to tear themselves with their nails. In children especially, black, bleeding, and excoriated points which are due to this cause, may often be observed on the face.

In some rare cases, there is neither any desquamation nor formation of scabs; the pustules sink in the course of eight and forty hours; there is then probably absorption of pus into the system; for a sudden prostration of the powers coincides with the shrinking of the pustules, and the phenomena observed, are in other respects analogous to those that occur in the animals into whose veins purulent matter has been injected.

Fever of great severity and violent cerebral symptoms may occur at this period; convulsions and profound coma, when they supervene, are speedily followed by death.

When the scabs are completely thrown off, the surfaces are covered, have a vinous-red tint, which only disappears with extreme slowness. In proportion as this red tint fades, the pits or scars left by the disease, become continually more apparent. These are always more numerous on the face than on other regions of the body, and there occasionally form a succession of seamed and puckered cicatrices which disfigure the countenance dreadfully. (a)

(a) The following brief description of small-pox, being the result of very ample opportunities of observation enjoyed by me in the epidemic, as it presented itself in Philadelphia in 1823-4, may not be without interest to the readers of these pages.

"In the premonitory symptoms, constituting the characters of the fever precursory to the eruption, there was considerable uniformity: the complaint of nearly all those attacked being at first chills and rigors; pains in the loins, head and limbs, with thirst and want of appetite; with which were soon associated gastric uneasiness, and in many, soreness of throat, rendering deglutition painful, hoarseness and weeping eyes. The duration of these symptoms, aggravated by febrile exacerbations, varied from one to three days, more usually the latter, after which the eruption begins to appear. It is first seen round the forehead and temples, near the hairy-scalp; then on the cheeks and breast and back; on the arms near the shoulders; the abdomen and thighs; and subsequently on the forearms and hands, and finally on the legs and feet. The appearance of the eruption is that of red or scarlet papulæ, presenting to the touch a sensible resistance, but not much raised, and without roughness or hardness. These papulæ, becoming more and more defined and elevated, are after a day or two converted into vesicles, with small elevated centres or bodies of a yellowish-white, and more diffused red and somewhat hard bases or margins. The redness extending as the eruption becomes copious, converts the skin, especially of the face, neck, and hands, into a red ground, from which project, in relief, the whitish vesicles. Similar appearances, but of a less marked nature, owing to the eruption being more scattered, are found on the trunk. The vesicles containing at first a thin, semi-transparent fluid, become gradually larger, fuller and yellower, and filled with a thick tenacious matter. This change is completed, and the pustules are entirely formed, after a lapse of time from the first eruptive effort, which varies from the fifth to the ninth day, and is occasionally longer. The mean for the beginning of maturation, or the finishing of the secretion of matter in the pustule; may be received as five days for the face, and eight or nine days for the body generally. The stages of the eruption, as regards its appearance, may be very properly called papular, vesicular, and pustular. This last having attained its height, completes what is termed the period of maturation, during which the pustules retain their fulness and spheroid figure, and exhibit the greatest proportion of whitish-yellow shining surface of their body, and diminished extent of redness at their base. A yellow dry point on the summit of the pustule, which loses thereby somewhat of its former spheroidal shape, by becoming flatter, or slightly indented, indicates beginning desiccation, at which time the body exhales that peculiar odour so unpleasant and so readily recognizable after it has once been perceived. There is no uniformity in the size of the pustules on the body generally, nor any equality among them on a particular part; more usually one larger and fuller is surrounded by others less so. Nor is it to be supposed that the changes above mentioned are gone through in regular suc-

The *diarrhœa*, when it has been present from the beginning of the disease, as often happens in children, continues, or becomes more profuse during this stage; occasionally the evacuations are even sanguinolent; or otherwise the cough becomes more troublesome, and a *pneumonia*, more or less decidedly characterized is set up. These different affections always correspond in severity with the nature of the variola, and the constitution of the individual. After the detachment of the crusts, especially among children, it is less common to witness subsultus of the tendons, convulsions, drowsiness, coma, or any approach to the apoplectic state.

It is at a generally somewhat advanced period of this stage that what are styled *nervous* symptoms commonly appear. These have been referred to cerebral irritation; but they occur more regularly than in true meningo-cephalitis, and they bear no relation to the swelling of the face, which by this time has disappeared. This is also the stage of the disease at which *OPHTHALMIA* so frequently supervenes. It is often difficult to learn whether this affection be pustular or not; because, whilst the eyelids are swelled, the presence of pustules upon the conjunctiva cannot be ascertained, and at the period when the tumefaction of the eyelids subsides, the pustules are resolved. The course of ophthalmia occurring under such circumstances, is insidious: within an interval of twenty-four hours the cornea has been found softened and opaque, in cases where previously no trace of injection had been perceived. In other cases this

cession on all parts of the surface, uniformly. It was no uncommon thing to see the eruption papular on the legs, vesicular on the trunk and arms, and pustular on the face, at the same epoch. One part even, as the arm for instance, has exhibited to us the three forms at the same time.

"Maturation complete and desiccation going on, the pustules break, and have their thin coverings converted into a yellow hard coat or crust, to which adheres the pus that was not removed by absorption, and the residue by evaporation of its watery part, is now converted into a scab of varying thickness, firm and prominent in its centre, and made up outwardly of concentric circles. The margins of the pustules, before of a distinct red, now assume a bluish-red or purplish-colour, and the skin begins to desquamate.

"The constitutional sympathies, or the symptoms in the milder and regular variety of the disease, are not of any great violence or intensity. The premonitory pains, diminishing or disappearing, after the coming out of the eruption, leave in their place a regular fever. The action of the heart and capillaries is hurried during the papular and vesicular stages; but becomes more equable while maturation is going on. During the former period, the loaded and not unfrequently furred tongue evidences disordered stomach, the cravings of which are for cold drinks. The somewhat laborious respiration may, in some cases, depend on the swelling and soreness of the fauces and pharynx; in others, on the eruption extending along the lining membrane of the larynx; whilst in others, it may be caused by bronchial engorgement."

"The febrile symptoms which abate during the process of maturation, are apt to return during desiccation; and when the skin begins to desquamate, then they constitute what is called secondary fever. The skin which had suffered so much, occasionally exhibits at this time an erysipelatous blush, accompanied by an inflammation of the subjacent cellular tissue, and the formation of troublesome boils, or infiltration of serum, especially where there is much laxity of structure, as in the eyelids, cheeks, lips, &c. The cutaneous system, during and immediately after the removal of its cuticle, and much of its rete mucosum, is of course very sensible, as well to the impression of clothes as to atmospherical extremes, and particularly cold. This is with many a critical time. It not unfrequently happened that persons, who had passed through the different stages of the disease and were advancing rapidly to convalescence, were suddenly seized with an affection of the chest,—pleurisy, bronchitis or pneumonia, and speedily carried off by the violence of the inflammation. The skin, exquisitely sensible in its denuded state to atmospherical vicissitudes, transmits with great promptness the morbid impression to the lungs, already prone to take on disease, in consequence of the active part they are compelled to play during the eruptive fever."—*North Am. Med. & Surg. Journ.*, July, 1826-7.

membrane is perforated by ulceration, and a staphyloma shoots forth; small phlegmonous abscesses are now also frequently developed on the head, neck, or extremities, as are pustules of ecthyma, furuncles, and the bullæ of rupia, which are succeeded by excoriations and sores of various depths and degrees of intractability, causing sleeplessness, and wearing out the strength of the patient. Lastly, chronic inflammations of the mucous membranes of the bronchi and intestines, are the severest of all the secondary affections of small-pox, and those which most frequently protract the convalescence. Phthisis pulmonalis has in general been observed to be accelerated in its progress by the influence of variola; in a few rare cases, however, the progress of pulmonary tubercles has appeared to be favourably modified by this disease.

It occasionally happens, however, that no serious symptom is observed in the first, second, and third periods of small-pox. Although confluent, the disease seems at times to be running its course with perfect regularity, when the patient suddenly sinks and dies, without our being able to detect, from a post-mortem examination of the body, any morbid appearances sufficient to account for this rapid and disastrous termination, which is then probably owing to the fatal action of the variolous poison upon the economy at large.

410. *Distinct and benign small-pox (variola discretæ benignæ, Burserius)*, is usually preceded by general symptoms of less severity, but of equally long continuance as those of the *confluent variola*.

On the first day of the invasion, we have shivering fits, alternating with flushes of heat, general uneasiness, and loss of appetite; on the second day, distaste for food of every description, nausea, hot skin, occasionally pain of the epigastrium, especially on pressure, a sense of heat in the stomach and pharynx, great thirst, redness of the point of the tongue, the middle and base of which are covered with a white or yellowish fur; next headache, drowsiness among children, disposition to perspire among adults, frequency of the pulse and respiration, restlessness, yawning, and pain in the back and loins, joints and limbs universally.

On the fourth day, the eruption is proclaimed by a number of small red, isolated spots, similar to flea-bites, upon the lips, then on the face, chin, neck, breast, abdomen and extremities. Next day, the rash is thicker, the spots are more prominent, and apparently *papular*. Their apex then becomes *vesicular* and transparent. On the third and fourth days of the eruption, the spots appear distinctly pustular, are well defined upon the skin, and, occasionally, on the mucous membrane of the mouth, pharynx, eyelids, prepuce and female labia. The pustules of these parts differ from those of the skin; for when the epithelium covering the whitish circular spots which characterize the pustules in these situations is removed, neither serum nor pus is found underneath it.

The integuments in the spaces between the pustules are frequently red and swollen. The pustules appear hard to the touch; the fluid they contain grows thick, becomes yellow in colour, and is not long before it acquires a perfectly purulent appearance. The pustules have a well-marked umbilicated form. The swelling is greatest in the face, although the pustules are commonly less numerous there than elsewhere; this part also becomes the peculiar seat of a tensive pain and burning heat. A *secondary fever* now (fifth day of the eruption) arises, and continues during the course of the suppuration of the pustules. The swelling of the face appears at first about the upper lip and ææ of the nose; it extends in succession to the lower lip, the cheeks, eyelids, and temples. At the same time, a slight ptialism occurs, even when no pustules have been thrown out upon the mouth. This state of things continues till towards the eleventh or twelfth day (eighth of the eruption); the *desiccation* of the pustules then takes place. The swelling of the face begins to subside, and the pustules to shrink, and subsequently to dry. The scabs are thrown off on the fourteenth or fifteenth day. Those of the hands are formed and detached three or four days later. There is a particular circumstance, and it is a remarkable one, which may accelerate the progress of the pustules; this is the existence of inflammation in the parts where they are evolved. Thus when individuals labouring under psoriasis, lichen, or chronic eczema, are attacked with small-pox, those pustules which appear on the parts already inflamed, very commonly run through the whole of their stages within eight days.

After the fall of the crusts, circular red marks of a brownish-red colour, and small irregular cicatrices, which are more especially conspicuous on the face, remain. These marks are occasionally afterwards affected with a furfuraceous desquamation.

411. The distinct small-pox may be attended with very severe symptoms, so as frequently even to prove fatal (*variola discretæ malignæ, Burserius*).<sup>1</sup> In these bad cases *nervous* symptoms are often observed, as also passive hemorrhages, petechiæ, dysentery, pneumonia, &c., complications which are more frequently seen in the confluent variola. (a)

412. The *inoculated small-pox* differs in several particulars from the natural disease. This variety is produced by introducing the variolous poison into the system, by applying it to an abraded surface by rubbing it upon the skin or mucous membranes, by inserting it, in fine, by means of the puncture of a lancet under the epidermis.

During the first, and occasionally even the second day of the inoculation, no change is perceived in the punctures; on the second or third day a slight itchiness is felt, which precedes the appearance of small spots of an orange or tawny-red colour. On the third day these spots enlarge. On the fourth, the redness of the spots increases, and a sense of tingling or pricking takes the place of the pruritus; the punctures become prominent and lenticular. On the fifth, the pricking sensation is more acute; local inflammatory symptoms are more strongly marked. On the sixth, the spots contain a transparent fluid in their apices. On the seventh, they grow white and purulent, and show a depression in their centre; the pain extends along the inner side of the arm, when the punctures have been made on this member, as is usual; the spots become phlegmonous, and are surrounded by a livid areola. On the eighth, slight shivering fits take place, the skin feels hot, there is headache of varying intensity, listlessness and want of spirits, nausea, now and then actual vomiting at intervals during four and twenty hours, and drowsiness. On the ninth, the inflammation of the inner part of the arm and axilla abates, the livid colour of the areola fades; the pus is dried up; occasionally the neighbouring pustules, when more than one puncture has been made, unite and form one thick and large crust, which is detached between the twentieth and twenty-fifth day from that of the inoculation. In this case, a broad and deep cicatrice is left upon the point inoculated, very similar to that which results from an issue.

Besides the *local variola*, whose history has thus been traced, another and *general eruption* appears upon the twelfth day of the inoculation, having been preceded by many symptoms of general functional derangement, analogous to those which go before the development of the natural small-pox. A crop of pustules appears on the face, neck, trunk, and limbs; this is usually but scanty: the pustules of inoculated small-pox are rarely numerous, and still more rarely confluent. The general eruption is commonly finished on the thirteenth or fourteenth day from that of the inoculation. The pustules arise, become depressed in their centres and semi-globular, like those of the natural small-pox. A purple areola surrounds their base; they become turgid with pus; the red circle which surrounds them fades at the same time that their centres whiten; the pus assumes a yellow colour, a small black point forms in the middle of each pustule, the areola of which has now disappeared. Their surfaces shrivel at length, and the pus they contain dries up and forms scabs of a grayish-brown colour, which, falling off in due season, leave behind them spots of a deep red hue, and occasionally superficial cicatrices.

413. Inoculated small-pox is not without its varieties:—

1. The secondary eruption may not happen, and the inoculation does not then prove effectually preservative.

(a) The varieties of small-pox, deduced from its external characters, which I described in the paper already quoted, were, the *confluent*, the *roseolar*, the *tuberculous*, and the *erysipelatous*. The tuberculous variety was most common in negroes, and was distinguished by hard, rough and knotted prominences, flattened in the centre, and containing little or no pus.

<sup>1</sup> Ponticelli (Silv. Ant.). Infortunii del vajuolo e metodo di andarne al riparo, 8vo. Parma, 1761, cap. iii.—Morton. Exercit. iii. cap. vi. vii. viii.—The anomalous variolæ observed by Sydenham in 1670, 1671, and 1672 (*variolæ nigre*), must be referred to the malignant distinct small-pox.

2. More rarely, there are no pustules developed in the situations of the punctures, and the secondary eruption does not the less take place.

3. The secondary eruption may appear in several successive crops.

4. The course of the eruption may be so accelerated, that within the space of eight or nine days, the disease passes through the whole of its periods, like varicella or modified small-pox; and, on the contrary, the pustules may be more tardy in their progress than in the natural small-pox.

5. And lastly, inoculation may be followed by a variolous fever without eruption.

Inoculated small-pox, as has been said, is generally distinct. The period of suppuration is not characterized by any violent symptoms. This variety of small-pox is occasionally complicated with an inflammation of the exanthematous kind (*roseola variolosa*, 268). It is much less frequently associated than natural small-pox with serious inflammatory affections of the mucous membranes, or other accidental complications of importance.

414. *Variolous fever, (variola sine variolis)*. This variety of the variolous contagion has been pointed out by several observers.<sup>1</sup> The resemblance which the symptoms of this fever bore to those of small-pox, induced me, says Sydenham, to give it the title of *variolous fever*, which indeed seemed so much the more appropriate, as the fever raged at the same time with small-pox, and got well under the same treatment; the two diseases belonged evidently to one family; and there was no difference between them, saving that in small-pox the morbid matter was directed towards the skin in the shape of an eruption, whilst in the variolous fever this matter was expelled from the system by the salivary glands.<sup>2</sup> Several inoculators assure us, that they also have seen these variolous fevers;<sup>3</sup> and some have added, that they gave subsequent immunity from small-pox.

I have not myself observed any fever of this description; perhaps it has escaped my notice, and I have not looked for it with sufficient attention.

415. *Anomalies of small-pox, and of the variolous pustule*.—The pustules of small-pox have not all the same course; some of them advance and terminate at the usual period; others having got half or a certain way, to the tenth, eighth, sixth, or even only the fourth day, the period at which true pus begins to be formed in their interior, stop short in their progress, shrink, suppurate no farther, and instead of pus, contain but a small quantity of coagulable lymph. This variety of pustule seems to me to correspond to *papular varicella*.

In other cases, a kind of double suppuration seems to take place, or rather the period of suppuration is prolonged beyond its usual term.

The secondary fever has been said to be wanting in some cases of small-pox; these, however, ought to be regarded as cases of the varioloid or modified disease.

416. Independently of the inflammation of the mucous membranes, which ought to be held one of the elements of variola, the disease may be complicated with other affections—with measles and scarlatina, purpura, croup, and pneumonia, more rarely with hæmoptysis, meningitis, &c., which may occur before and during the eruption, or the desiccation, and after the detachment of the scabs. These complications are particularly to be dreaded during very hot or very cold seasons. The fear of death, and other violent moral affections, frequently give rise to such a state as is promptly fatal.

During convalescence, erysipelas, furuncles, and phlegmons of the legs, thighs and arms, are very commonly observed; ecthyma appears upon the extremities; chronic inflammation of the intestines, in fine, often protracts the cure, and even leads to an unfavourable termination. I shall by and by point out the best remarks that have been made in regard to these complications and secondary affections.

417. *Alterations of structure*.—The pustules of small-pox are commonly more confluent and farther advanced on the face than on other parts; they are also flatter there than elsewhere, and occasionally

form a sort of whitish layer spread over the whole face and forehead. If death occurs at a later period of the disease, the pustules are already dry upon the face, where they form a kind of bluish scab, whilst, over the rest of the body, they are still at their height. The surrounding skin continues white or very slightly tinged with violet. On other parts of the body the pustules are for the major part umbilicated; their centre, slightly depressed, is in general of a little less dead white colour than the rest of their superficies; at other times, and especially upon the legs, they are of a vinous red or dusky brown colour.

The pustules, at the period of their height, feel hard and solid under the finger. Those of the palms of the hands are usually of considerable size, slightly rounded, and without any depression in the centre; their colour is not of quite so dull a white as the pustules in general. The pustules of the soles of the feet are either not raised at all, or but very slightly so; they appear through the thick cuticle of this region, under the form of circular obscure violet-coloured spots, surrounded by a border of a deader white colour than the rest of the skin. The pustules of the penis and scrotum are usually small, and feel very firm to the touch.

Some pustules have a follicular orifice about their middle, from which sprouts a hair; the greater number, however, present nothing of the kind. On cutting them across, the following appearances present themselves: the subcutaneous vascular rete seems very much developed in places; but this is far from being invariably the case. The deep layer of the corion, in which the middle of each pustule is situated, is always very much injected, and looks as if it were suffused with blood; occasionally, indeed, it presents a red, streaked and punctuated appearance. The outer surface of the corion, in which the general surface of the pustule has its seat, is swelled, slightly transparent, and yellowish in colour. Above the corion we meet with a pseudo-membranous layer, which forms the substance of the pustule. It appears in the shape of a truncated cone, about half a line in thickness, more or less, according to the size of the pustule. It is a substance of a dull white colour, of some consistency, but rather friable, and intimately connected with the inner surface of the cuticle, with which it appears to be confounded; it is less adherent to the surface of the corion. In pustules that are farther advanced, a few small vacuities are perceived, or a waving line, or small winding cavity is seen between the outer surface of the dermis and the adventitious white layer of which mention has just been made. These intervals, or this cavity, is found full of a serous fluid. In the pustules of the face, farther advanced than those of the other regions, this fluid becomes opalescent, and is more abundant, occurring not only in the cavities of the pustules, but effused below the cuticle of their circumference. The cuticle thus raised may then be detached in shreds of considerable size. Beneath it, in situations corresponding to the pustules, a great number of irregularly rounded prominences are observed, separated from each other by sinuous furrows of the skin.

This eroded appearance of the dermis only occurs in those places that are beset with pustules in a state of suppuration. The cuticle appears thickened in some degree, but maceration shows that this is not the case.

In the situation of the beard, the cuticular canals of the hairs appear under the form of opaque white lines, traversing the substance of the skin, and ending at a species of white bulbs, bearing a pretty strong resemblance to the figure given of them by Cotugno.

418. After macerating portions of the skin of individuals who had died under small-pox, in water for several days, Mr. Young and I observed the following appearances: the cuticle was detached with the slightest touch, and always presented on its surface the *elevations* and *opaque white-coloured* spots of the pustules. This dull white was visible over the whole surface of a certain number of the pustular impressions; but in the majority it either diminished considerably or ceased entirely towards their centres, thus preserving the umbilicated character. The inner surface of the cuticle presented nearly the same appearances as depressions, which on the outer surface were conspicuous as elevations; the pseudo-membranous layer to which the pustule at its height owes its umbilicated form and dull white colour, was here found in a manner isolated and distinct. In the

<sup>1</sup> Sydenham. Opera. Sect. iii. cap. iii. p. 181, edit. Patav. 1700.—Ludwig. Instit. medicin. clinic. Pars. i. cap. i. subsect. vii. §. 167.—Azzoguidi (Germ.). Lettera sopra i mali effetti dell' inoculazione. Venez. 12mo. 1782.

<sup>2</sup> De Haen also says that this species of fever is attended with pyalism, like confluent small-pox. Divis. Febr. p. 97.

<sup>3</sup> Fouquet. Traitement de la petite-vérole des enfants, p. 123, 12mo. Paris, 1772.—Gatti. Nouvelles reflexions sur la pratique de l'inoculation, 12mo. Bruxelles, 1797.—Dézoteux et Valentin. Traité de l'inoculation, p. 297.

hollows, indeed, a kind of disc or ring of a whitish, pseudo-membranous matter was found, which could easily be removed by scraping; the cuticle always remained a little depressed, but it preserved nearly its natural appearance. The piliferous ducts which passed through several of these discs, were whiter, larger, and more conspicuous than those that were visible upon the surrounding cuticle.

The annular disposition of this white substance was particularly remarkable in the pustules of the soles of the feet. Here too the false membrane, stopping abruptly at the circumference of the pustule, produced the white border which we had remarked during life. The outer edge of this pseudo-membranous ring was more prominent than the inner margin, so that a kind of cupped appearance was produced, and a piece of the cuticle of the sole of the foot, pretty numerous beset with pustules viewed from the inside, bore a strong resemblance to the surface of a laden honey-comb. When this false membrane was removed, the inner surface of the epidermis looked of a very faint whitish colour; an appearance which might perhaps be ascribed to the presence of the deep epidermic membrane.

The skin of the palms of the hands presented the same appearances, but these were here less strongly marked.

The outer surface of the dermis or corion, in those places corresponding to the centres of pustules, exhibited rounded eminences which contrasted strongly, by their yellowish colour and semi-transparent appearance, with the tint and character of the rest of the skin. These elevations were always of smaller dimensions than the alveolæ of the epidermis with which they were in relation. Around several of them a linear depression could be perceived, produced by the impression of the outer and prominent edge of the pseudo-membranous substance; it was observed more especially on the soles of the feet, where the outer rims of the discs, here slightly flocculent, were nearly half a line in thickness. These eminences, examined with the magnifier, presented the slight superficial grooves which separate the papillæ of the corion. This feature was especially remarkable in the palms of the hands and soles of the feet, situations in which the papillæ appeared to be increased in size.

This appearance was the same as that which was evident in the interior of the greater number of the pustules when arrived at their height; but in several pustules, farther advanced, the surface of the corion, instead of presenting these papillary risings, was on the contrary, more or less depressed; nevertheless, a slight elevation could still be discovered in the centre of a great many of the depressions. To conclude, the skin was in some places manifestly eroded.

The elevations observed in the pustules of the outer surface of the corion were softer, and much more affected by prolonged maceration (during a month) than the other parts of the skin. In the situations where they had existed, a brownish and soft depression was discovered, contrasting strongly with the dull white of the rest of the dermal tissue.

On examining those variolous pustules which had been touched with caustic very shortly after their development, during life, we found the crusts and squamæ of a deep brown colour, somewhat depressed, and dry on the exterior; their inner surface was yellowish. Under these squamæ the corion appeared to be more eroded than in other parts of the body.

To conclude, the size, the colour, and the umbilicated depression of the pustules of variola depend evidently on the pseudo-membranous disc, secreted by the papillary body, inflamed and elevated in the form of a zone, in the places occupied by the pustules.

When two or three pustules happen to have become united by their corresponding edges, the anatomical characters of each of the several pustules are often perceptible in the group. Scattered among the true variolous pustules we also frequently perceive *conoidal* or *globular* pustules precisely similar to those which characterize two of the varieties of *pustular* varicella. In fine, the skin of the face and posterior parts of the trunk is usually very much injected. (a)

(a) "The form of the pustule of small-pox is strikingly modified in reference to the seat of its development. Thus, on the face, where the pustules advance very rapidly to maturity, they are flat, and non-umbilicated. On the palms of the hands, and on the palmar surface of the fingers, they rise gradually from the surface, are but little raised

419. The *mucous membranes* present alterations which are not less remarkable than those of the skin. The conjunctiva, the mucous membranes of the nasal fossæ, mouth, pharynx, larynx, trachea, and bronchia, of the prepuce in the male and labia in the female, &c., are usually injected, and exhibit traces or rudiments of pustules. The nasal fossæ, of a bright red colour, are covered with thick mucus; the arch of the palate and upper surface of the tongue present gray pseudo-membranous exudations, or small flocculi of the epithelium. The mucous membrane of the mouth is of a livid red, and shreds of the epithelium and a gray pseudo-membranous deposit are observed as far as the eye can penetrate, hanging from the velum palati to the aryteno-epiglottidean ligaments. In cases of confluent variola, the interior of the larynx and trachea also presents unequivocal signs of inflammation: the mucous membrane is of a violet hue, with whitish or grayish points scattered over it, circular in shape, and varying from half a line to two lines in diameter, having a red, central point, without any epithelium, and several other spots, irregular in their shapes and of various sizes, probably consecutive to groups of coherent pustules. Whilst examining the body of a woman who had died on the fourth day of the eruption of a confluent small-pox, Chaussier<sup>1</sup> found a great number of pustules in the larynx and trachea *similar in size and shape to those which existed on the skin*. These pustules were not confined to the larynx and trachea; several were even found in the *principal ramifications of the bronchia*, on the inside of the mouth, on the pharynx and upper part of the œsophagus. I must, however, add to this statement, that in my own experience I have always found the variolous pustules of the mucous membranes differing in many respects from those of the skin. Thus I have never seen pustules in the larynx, trachea, and bronchia, *precisely similar* to those of the skin; that is to say, formed of a pseudo-membranous disc, with purulent matter deposited between the corion and cuticle; farther, the variolous pustules of the mucous membranes never become incrustated, and in several, the pseudo-membranous deposit is not even covered with an epithelium; lastly, they are not generally succeeded by visible cicatrices.

I have never seen variolous pustules in the œsophagus, stomach, or intestines; but I have observed that these parts were always inflamed in a greater or less degree. Cotugno informs us that he saw well-characterized variolous pustules on the mucous membrane of the rectum, in a case of prolapsus of this part;<sup>2</sup> in such cases, however,

above the level of the surrounding skin, and are also non-umbilicated. On the soles of the feet, again, they are large in extent, and still more flat than the preceding, appearing like purplish disks with a distinct white margin, and non-umbilicated. Usually, the umbilicated centre presents a reddish or brownish tint, and sometimes, though rarely, it is perforated by the shaft of a hair.

"When a well-formed and mature pustule is examined by dissection, it is found to be divided in its interior by a transverse septum into two chambers, both containing pus. The upper chamber is the larger of the two, and they communicate with each other, to a greater or less extent, by the rupture of the transverse septum around its marginal border. The epidermis, forming the superficial boundary of the pustule, is the segment of a sphere, and continuous by its circumference with the cuticle covering the adjoining skin. The transverse septum is a layer of false membrane, of a whitish colour, which was deposited on the dermis at an early stage of the pustule. Subsequently this layer becomes separated from the dermis, and raised by the formation of pus beneath it, and at the same time it is broken around its edges, and permits the pus of the deeper cavity to communicate with that already contained in the superficial chamber. In consequence of the peculiarity in the mode of its production, this layer of false membrane generally retains permanently the umbilicated form of the primitive pustule, and is thinner at the centre than towards its circumference. When this septum is removed, the deep chamber is brought into view, and the depressed and sometimes ulcerated base of the pock exposed. The surface of the base is of a bright or purplish red colour, and highly vascular." Wilson (*op. cit.*).

<sup>1</sup> Bulet. de la faculté de med. de Paris, 8vo. t. iv. p. 14.

<sup>2</sup> De Sedib. Variolar. p. 152, 12mo. Viennæ.

it is well known that the mucous membrane approaches the skin in its structure.

The mucous membrane of the stomach and bowels frequently presents spots of extravasated blood, and its follicles are enlarged and more than usually prominent; ecchymoses are also seen in many cases in the substance of the intestinal parietes, especially in *variola nigra*. The follicles of the mucous membrane of the great intestines are remarkably enlarged, of a violet colour, and flattened or projecting, when symptoms of a dysenteric nature have accompanied the disease.

420. In some subjects the blood has been found fluid, serous, and apt to penetrate the tissues; bloody effusions have also been observed in the subcutaneous and sub-serous cellular membrane, and in the substance of the corion; as also petechiæ and ecchymoses of the stomach; a sanguinolent loading of the lungs (*variola nigra*); and a remarkable pale and flaccid state of the heart, on the inner surface of which, small circumscribed violet or red-coloured spots have occasionally been discovered.

Gendrin<sup>1</sup> relates that having injected the blood of individuals labouring under confluent small-pox into the veins of animals, very violent and rapidly fatal symptoms were induced, and that on opening the bodies after death several organs were found very much inflamed.

It is more rarely that we meet with alterations of other viscera. In some small-pox patients who exhibited symptoms of meningitis, the membranes of the brain have been found to be injected, and effusions of a limpid or sanguinolent serum to have taken place between the convolutions, and into the ventricles of the brain, as well as the arachnoid membrane of the spinal cord. M. Berard found the arteries very commonly stained of a red colour in an epidemic variola which prevailed at Angers among a detachment of recruits. Messrs. Rigot and Trousseau<sup>2</sup> tell us, that having been present at the dissection of a great number of subjects who had sunk under small-pox, they almost uniformly observed a red colour of the blood-vessels, but in no instance did they find the parietes of the arteries thickened so far as sensibly to diminish the capacity of their canals. M. Tanchou<sup>3</sup> had before this period called the attention of pathologists to this red state of the arteries, which he attributed to inflammation. Upon one occasion, in 1826, when discharging for a time the duties of M. Bailly, at the Hôpital de la Pitié, I had several opportunities of observing this redness of the vascular parietes, which in the greater number of cases appeared to me to have taken place after death, and to be due to a particular state of the blood. I have, however, occasionally seen a redness of the arteries occurring in long patches, without there being any blood present to account for the phenomenon, in the bodies of subjects who, during their lives, had exhibited symptoms of *ataxic* or *nervous variola*. To conclude this subject, M. Costallat has observed gangrene of the lungs along with severe small-pox, and M. Fred. Cuvier, jun., has found small abscesses in the pulmonary tissue of those who had died during the suppurative stage of the disease, very similar to the purulent deposits encountered in these organs after unfortunate surgical operations on the limbs.

In all the varieties of small-pox which end fatally, the lungs are frequently found *gorged with blood*.

421. *Causes*.—Small-pox is a highly contagious disease; it is transmitted by mediate as well as by immediate contact; the contagion extends to some distance in the atmosphere and follows the direction of the wind. The contagious character is developed during the supuration of the pustules, and remains till the period of their desiccation. It does not appear to undergo any change from the individuals it affects or the varieties it presents; the pus and miasm of a confluent variola may communicate one which shall be distinct, and *vice versa*.

Small-pox spares no sex nor age, not even excepting the fœtus, which may be attacked through the medium of the mother, though she should not feel the effects of the poison, either from having been previously vaccinated, or had the small-pox naturally or by inoculation.<sup>4</sup> Such was the case of the mother of Mauriceau, according to Désormeaux:<sup>5</sup> she had been tending the eldest of her children, who died of

small-pox, and the day after this event she was delivered of Mauriceau, who, according to the testimony of his parents, came into the world with five or six distinct pustules of small-pox upon his body.

I am indebted to the kindness of M. Costallat for an opportunity of seeing a somewhat similar case: Rosalie L \* \* \*, aged twenty-four, presented a cicatrice on each arm nearly the size of a crown-piece, which appeared to have been produced by the fusion of several vaccine pustules into one. When about four months gone in her pregnancy she contracted small-pox along with three other individuals of her family, on the 6th of April, 1833. The eruption was characterized by large, distinct, flat pustules; Rosalie was so little incommoded that she went about her usual avocations, and it was only upon particular recommendation that she consented to keep her room for two or three days. After the 20th of April she mounted to a sixth flat, many times a day, to wait upon her father and husband. On the 28th she no longer felt the motions of her child, and on the 13th of May she miscarried. The whole surface of the fœtus was covered with variolous pustules perfectly well characterized.

Some privileged persons resist repeated inoculation, and even escape amidst variolous epidemics; but these individuals very commonly end by contracting small-pox at a later period of life.

The disease appears at all seasons and in every climate; it does not generally attack the same individual oftener than once; but we have well-authenticated instances to the contrary;<sup>6</sup> and some individuals even show a kind of predisposition to catch the disease a second and a third time.<sup>7</sup> (a)

Small-pox is occasionally *sporadic*; it, however, most usually occurs *epidemically*. It commonly commences its ravages in the spring, prevails during the summer, and disappears in winter. I have mentioned many small-pox epidemics which have occurred; in almost all of these have the divers forms of variola and its modifications, the varicellæ, been observed. Some of these epidemics were remarkable for their mildness, others as much distinguished for their malignancy, whilst several of them have appeared benign at one epoch of their continuance, and malignant at another.

422. *Diagnosis*.—Before the appearance of the eruption, the diagnosis of small-pox always presents much uncertainty, even when every attention is given to the character of the prevailing constitution or epidemic: the precursory symptoms of variola are common to many diseases; they acquire peculiar importance only when it is known that the patient has been immediately exposed to the influence of the variolous contagion.

The spots and papular rash which precede the formation of the umbilicated pustules may be distinguished from the spots of measles, as they feel granular, like small hard bodies under the finger; they are also evidently deeper, as well as firmer, than those of measles.

The umbilicated pustules of small-pox can only be confounded with those of pustular varicella, which present the same *flattened* appearance; these, however, are much less uniformly depressed in the centre, suppurate during a shorter period, and are of a duller white colour; farther, this species of varicella is not accompanied with any secondary fever. As to the other varieties of varicella, the points of difference are so many and so striking, that no mistake seems possible.

The pustules of small-pox are very unlike those of any of the other pustular diseases, particularly ecthyma, and do not differ less from the artificial pustules which are produced by mechanical irritation of the skin, and which have been very improperly entitled false inoculated small-pox. These eruptions, moreover, do not run any thing like the regular course of those of the eruptive fevers.

423. *Prognosis*.—Distinct small-pox, unattended with nervous symptoms, passive hemorrhage, dysentery, &c., almost always ends favourably from the fourteenth to the twentieth day. The duration of confluent small-pox is incomparably longer when the disease does not terminate fatally in either of its two first stages.

In the epidemic of Marseilles of 1828, the distinct variola did not

(a) We met with examples of a second attack of small-pox in the epidemic in Philadelphia in 1823-4.

last beyond the fifteenth day, whilst the confluent species went on to the thirty-first day, and even longer.

Even from the very commencement of the attack the course of the disease may be in some measure calculated, from the intensity of the initiatory symptoms: "*Quo febris variolosa mitior, eò eruptio parior, eò lenior status inflammationis, suppuratior.*"<sup>1</sup> As a general rule, however, it is advisable to be extremely cautious in the prognosis of small-pox.

The favourable or unfavourable chances of small-pox, in truth, cannot be calculated without a just appreciation of each particular circumstance after it has occurred.

If the eruption be successive in confluent small-pox, the danger is in general less imminent; if, on the contrary, the pustules appear at once on the face, neck, trunk and extremities, the disease proves one of the most formidable to which the human body is subject, and death is very frequently its consequence.

Cerebral symptoms (nervous variola) at the invasion and height of the disease are very alarming.

Ecchymoses and petechiæ frequently announce a fatal alteration of the blood, and approaching dissolution.

Variolous inflammation of the larynx and trachea, croup and pseudo-membranous bronchitis make the prognosis more and more unfavourable.

Obstinate ophthalmia, otitis, cæco-colitis, abscesses and other accidental affections, are the causes of additional symptoms which protract and increase the risks of the convalescence.

The precocious development of the eruption, the smallness of the pustules, a flatness in their form, irregularity in their periods, &c., have all been signalized as unfavourable symptoms. The danger has been held to be extreme, when the elevations were filled with transparent serum instead of pus; the occurrence of hemorrhage during the period of suppuration, has also been regarded as a very disastrous symptom. These notions are fortunately but too well founded, when such outward signs occur along with the deeper lesions of the mucous membranes or of the viscera, or along with nervous symptoms and altered conditions of the blood. Under other circumstances, however, it would be rash to draw such serious inferences from any irregularity in the progress of the disease. (a)

424. *Treatment.*—The variolous fever, and inflammatory actions of small-pox having necessarily to pass through certain stages before they can be resolved, we must be content with endeavouring to moderate the severity of the principal symptoms, and not attempt by any perturbing measures to prevent their evolution or cut short their progress.

Intervening diseases, not variolous in their nature, may be met by more active and more varied modes of treatment.

425. In benign small-pox the inflammation of the skin is always slight, and that of the mucous membranes of the air and alimentary passages is seldom of any severity; still, as there is no necessary and invariable ratio between these affections of the two orders of surfaces, it may chance that a small-pox, distinct externally, may be accompanied by internal lesions of such importance as to require the strictest watching.

If the fever be trifling, if the inflammation of the skin and that of the mucous surfaces which accompany it, be slight, we shall have little else to do than to see the patient placed in a large room, and in good air of a moderate temperature. If the appearance of the eruption be preceded by vomiting and pain of the epigastric region of considerable severity, it is advisable to apply leeches to this part, to cover the abdomen with emollient cataplasms, prescribing at the same time complete abstinence from food, acidulated drinks to quench

(a) The character of the prevailing epidemic, when small-pox appears in this way, the circumstance of the patient being in a hospital or crowded room, or in his own apartment, and the previous habits of those attacked are all to be considered in forming a prognosis. Within my own experience I found that the proportional mortality was greater among my patients in the hospital, than in dispensary practice. Drunkards among men and prostitutes among women rarely escape.

<sup>1</sup> Stoll. Aphor. de cognos. et curand. febr. Aphor. 538, 8vo. Vien., 1788.

the thirst, and mucilaginous glysters to empty the bowels. If the inflammatory symptoms do not yield, if they become associated with a variolous laryngo-tracheitis, and if their severity seems to prevent the free evolution of the pustules upon the skin, general blood-letting ought to be practised, unless the application of a larger number of leeches to the scrobiculus cordis and fore part of the throat be preferred. When the eruption is complete, and the progress of the internal inflammatory affections is arrested, we have only to watch the further progress of these diseases, the symptoms of which soon begin to decline, and finally disappear under the influence of low diet and diluents, and by the natural progress of the disease.

426. The treatment of the severer cases of variola is attended with more difficulties.

1. The whole surface of the body is occasionally covered with pustules; the subcutaneous cellular tissue is greatly swollen; the parotid and sub-maxillary glands are enlarged, and variolous inflammations are set up in the mouth and nasal fossæ, on the conjunctivæ, pharynx, larynx, trachea and bronchia, and occasionally even in the stomach and intestinal canal (*inflammatory variolæ*). In this case, especially if the patient be young, the inflammatory condition must be modified by the abstraction of blood generally and locally, by oily and emollient embrocations, such as soft cerate or cream applied either cool or cold, and by the use of the temperate bath; the latter means has often appeared to me extremely beneficial in these varieties of small-pox. When the disease has attained its suppurating stage, the pustules should be punctured with the point of a needle, and the matter they contain suffered to escape and afterwards absorbed by a sponge dipped in some emollient decoction.

2. This purely antiphlogistic plan also appears to me preferable to any other in those cases where the disease wears a formidable aspect, from the intensity of the variolous inflammation of the air-passages, evinced by the dyspnœa which then accompanies the development of the eruption, and the livid tint of the pustules themselves (*laryngeal variolæ*).

3. As to *nervous variolæ* I feel truly at a loss to lay down any rules for their treatment. Patients sink when they are bled, and almost always die when treated upon other systems, such as the exhibition of camphor, assafoetida, valerian, oxide of zinc, &c., medicines, the whole of which have been very generally recommended. In these untoward cases I have frequently had recourse to the application of ice to the head, combined with diluents, and the administration of calomel in laxative doses. But this method, like all the rest, is but too frequently unsuccessful.

4. When confluent small-pox is accompanied with petechiæ, ecchymoses, epistaxis, and other hemorrhages analogous to those which are observed in purpura hemorrhagica, and which are very commonly attributed to an alteration of the blood, the use of purgatives, and of the acidulated decoction of bark, seem preferable to the antiphlogistic plan alone. Under all circumstances this variety of small-pox is almost uniformly fatal.

427. Other general plans and particular means have been recommended; but the circumstances which especially or exclusively require their employment have not been determined in a very precise manner. Thus, with a view to diminish the violence of the eruption and the symptoms which attend it, some have proposed to expose patients to the cold air, to plunge them into a cold bath, and to sprinkle or sponge the surface with cold water. The last-named measure never makes the pustules disappear, as some pathologists have expressed their fears it would; but I have known it aggravate the symptoms of the laryngo-bronchitis, which, in a greater or less degree, always accompanies confluent variola. I have not, however, seen it tried sufficiently often to have made up my mind as to its advantages and inconveniences. Some physicians,—De Moneta, Ploucquet, and Hoffmann, have advised the use of cold applications to be restricted to the face.

428. Several practitioners have supposed that they could cut short the course of the pustules by the free use of venesection. M. Janson states that a number of leeches, having been applied to the throat of a little girl labouring under confluent small-pox, gave occasion to a violent hemorrhage by which the patient was brought into great jeopardy, but which had the effect at the same time of causing the greater

number of the variolous pustules to die off. This fact, however, and several others, analogous in their nature, by no means authorize indiscriminate attempts to cut short every case of confluent small-pox by copious and repeated bleedings; the method, first recommended by De la Metrie, pursued as a general rule, would certainly be hurtful; but such cases should embolden us to deplete freely at the commencement and during the eruption of coherent small-pox of a decidedly inflammatory character, accompanied by erysipelatous puffing of the face, congestion of the brain and laryngo-tracheitis.

Pediluvia have been recommended in the hope of diverting the eruption to the lower extremities especially; I have never seen this expectation realized. Dr. Delaroche, of the Maison Royale de Santé, directed the application of blisters to the legs with better success.

When the eruption of small-pox appears slowly or with difficulty, and especially when this delay appears due to the impression of cold, as occasionally happens in winter among the poorer classes, some practitioners advise recourse to be had to the warm and vapour bath; others recommend emetics, and others sudorifics, such as the acetate of ammonia: I have seen too few of these tardy eruptions to feel myself in a position to recommend in particular any one of the plans mentioned.

Mercurial preparations internally and externally have been much lauded, as preventing or lessening the violence of the variolous eruption; I have not myself tried them to a sufficient extent to enable me to venture an opinion upon their efficacy.

Purgative medicines have been recommended in confluent small-pox to diminish the violence of the eruption, and even to make it abort entirely; further experiments on the value of this idea require to be made. Purgatives are frequently of use at the period of suppuration, to lessen the pyalism and inflammatory affections of internal organs so apt to show themselves at this stage; they have also been particularly prescribed with a view to prevent verminous complaints, which are extremely rare at the present time.

Tonics—wine, the bark, the mineral acids, and camphor internally and externally, may all become useful at the period of suppuration and desiccation, especially to the aged, and to cachectic children, or when the disease assumes a *putrid* or *hemorrhagic* character (Sydenham, Fouquet).

Opiates, especially by way of injection, are useful when dysenteric symptoms complicate small-pox; and they have been recommended during the state of insomnia and delirium that accompanies the confluent disease (Sydenham, Stoerck). In these alarming cases, however, their advantages have often appeared to me questionable.

429. Symptoms of small-pox having once been declared, is there any mode of diminishing the virulence of its poison? Some physicians have maintained the affirmative of this proposition. Moublet<sup>1</sup> asserts that we may cut short the disease, or at least produce at our pleasure, *variola sine variolis*, by evacuating the virus with emetics and purgatives. De la Metrie believed that he could attain the same end by copious venesection, and this notion has been again brought forward in these latter times. Eichhorn is of opinion that the disease may be made to abort by the free use of the mineral acids, and of calomel and antimonial preparations exhibited from the invasion of the primary fever. He also sets forth another piece of practice, which, according to him, has great influence in rendering small-pox more benign. This consists in *making from forty to fifty incisions on the person of the patient*, as soon as the symptoms of the primary fever are discovered, or even when the eruption begins to appear on the face in the form of small hard papulæ, *into which as great a quantity of the vaccine virus as possible is to be introduced*; and he assures us that if the medical attendant have been called in time to do this, it will be his own fault if he ever lose a patient from small-pox. I have tried this practice on two occasions; but both of the patients died, the one of the confluent, the other the nervous form of the disease. The stigmata of the eruption, however, were conspicuous over the whole body at the time the vaccine inoculation was performed, and it was perhaps too late to give the operation a fair chance of succeeding; it was also done with vaccine matter preserved

between two plates of glass, and Eichhorn recommends the virus to be transferred directly from the vaccine pustule to the punctures.

I must add that the experiments of Woodville, Willan, and M. Herpin upon the reciprocal influence of the variolous and vaccine virus, appear to favour the idea of Eichhorn, and I should, for my own part, certainly put the plan in practice as often as the opportunity for doing so occurred.

430. The *local* treatment of variolous pustules has been the subject of numerous experiments.

During the suppurating stage in adults, and especially in children, it is proper to wash the eyes frequently, with some emollient decoction, and to cleanse and unplug the nostrils by instilling fluids of the same description from time to time. The heat which is complained of in the inside of the mouth may be lessened by washing or garbling repeatedly, and by making patients sip a little cool drink at frequent intervals. It is also proper to prevent children from scratching themselves, and should the skin appear in any place excoriated or ulcerated, it must then be dusted over with fine starch or the powder or lycopodium. Cotugno further recommends the pustules to be frequently bathed in order to accelerate their progress, and to render the pits less apparent afterwards. It was the practice formerly to follow the advice of the Arabian physicians, and open the pustules arrived at the period of suppuration, to squeeze out the pus they contained, and then gently to bathe and cleanse the surface with tepid milk and water, decoction of mallows or of poppy-heads. This system has always appeared to me to be beneficial: a patient who was under my care in the Hôpital St. Antoine, on account of a very severe confluent small-pox, evidently owed his recovery to the zeal and attention of Dr. Bonnet, of Poitiers, who expressed and wiped away the matter from the whole of his pustules.

Hufeland and Tournay recommended the pustules to be laid open, and Mr. Stewart, in 1829, proposed to plunge the point of a needle into the variolous elevations on the first or second day of their appearance, and by compression to force out the serum or blood which they contained. This measure does not seem so good as the system of cauterization to be mentioned immediately.

With a view to check or modify the eruption, some practitioners have advised the skin to be briskly rubbed with a coarse towel, a short time after the appearance of the pustules. This recommendation is now never acted on.

431. Messrs. Bretonneau and Serres have proposed *cauterization with the nitrate of silver* as a means of cutting short the progress of the pustules of small-pox. M. Bretonneau recommends the apices of the pustules, shortly after their appearance, to be transfixed and removed with a needle of gold or silver charged with nitrate of silver. M. Velpeau advises the summits to be first removed, and the exposed points to be then touched with a sharp pencil of nitrate of silver, or a fine probe charged with a solution of this substance, which is to be plunged into the centre of the pustule, the surface being subsequently farther cauterized by the application of the caustic in substance. Others again have held that it was better to cauterize the pustules *en masse*, with a camel's hair pencil dipped in a solution of nitrate of silver, containing about a scruple of the salt to an ounce of distilled water, and to repeat this application if the first did not seem effectual.

432. If, during the course of the first and second day of the eruption, the variolous papulæ be deeply cauterized *individually* after opening their apices with the point of a lancet, they are often completely arrested in their progress. About the seventh day the cuticle which has been exposed to the action of the caustic, falls off in plates, generally without leaving any apparent cicatrice. If the pustules are not treated with the caustic sooner than the third day, they frequently do not miscarry completely, and if the measure is not attempted earlier than on the fourth and fifth day, the operation then fails to check the progress of the inflammation, and the pustules are followed by cicatrices.

The plan of cauterizing *en masse* is less painful and much more expeditious than the preceding one, which requires long hours to touch the whole of the pustules even of the face, in a confluent case. The general application of the caustic, however, scarcely ever puts a complete stop to the progress of the pustules when it is done even so early as the first or second day of the eruption. It suspends, indeed,

<sup>1</sup> Journal de Méd. t. xvii. 1762.

to outward appearance, the march of the eruption, but when the crust produced by the caustic, comes to be detached, traces of variolous pustules which have continued to advance unmodified through their regular stages, are discovered beneath it.

To sum up, on this head, then, it appears: 1. That the general cauterization of the pustules can only be advantageously instituted on the first or second day of the eruption. 2. That the application of the caustic solution should be restricted to those places which we are interested in preserving free from cicatrices; for the pain that attends the operation, and the reaction which follows it, induce me to believe that the cauterization of a large extent of surface would be more likely to cause than to prevent affections of the brain. 3. Lastly, the sole incontestable advantage of the *individual* cauterization of the pustules, performed in time, being to preserve the skin from cicatrices, the *ectrotic* method appears to me applicable rather to those pustules evolved upon the face in distinct or semi-confluent small pox, than to the coherent pustules of the most serious varieties of the disease. (a)

(a) Among the means of abating the eruption and preventing the subsequent pits from small-pox, are the exclusion of light from the sick room, and covering the skin, as that of the face, with gold leaf, directly upon the invasion of the disease, and continuing the application, by renewal every morning and evening, until the end of maturation and the suppurative fever. The same good effects are represented to have been obtained by anointing the face of those who had small-pox with sweet oil. Another means of carrying out the ectrotic method, is by the application of sulphur ointment, slightly rubbed over the entire cutaneous surface, as recommended by Dr. Medivaine, of Ghent. The ointment is composed of two drachms of sulphur to one ounce of lard; and it is to be used three times a day, at as early a stage of the disease as possible.

A still more important ectrotic remedy is found in the external application of mercury by plaster or even ointment. M. Briquet (*Archives Générales de Médecine*, Octob., 1838), points out the details and advantages of this practice in the treatment of all the varieties of small-pox, whether simple, confluent or modified. "The effect of these plasters is, in general, either to prevent the development of the pustules, or so to modify them that they become mere abortions, and very slightly affect the skin. M. Briquet details several cases which support him in his opinion that mercury, locally applied, exercises great influence on the course and nature of the eruption. By the application of the plasters the exanthema either undergoes complete resolution, or it is converted into vesicles or tubercles. The resolution is either primitive or secondary. The former takes place when the plaster has been applied whilst the eruption is still papular, and its effect is the complete disappearance of a number of papulæ, which, without the application of the plaster, would have passed into pustules. This diminution of number, as ascertained by counting the number of papulæ before and after the application of the plaster, varies from a third to a tenth of the whole number. Secondary resolution ensues, when the papulæ, after being covered by the plaster, increase in size for two days, and then pass into resolution. But the most general effect of the plasters is to produce conversion of the eruption into a vesicular or tubercular form. The vesicular is the more common, and in such cases the eruption bears considerable resemblance to herpes, or to vesicles which have been developed under a cataplasm. The vesicles, when they have reached their maximum development, contain a milky fluid; their walls are formed by an epidermis extremely thin, and not at all tense, and their base is sometimes surrounded by a slight areola of a pale rose colour. They vary in size; the smallest are not larger than the point of a pin, the largest equal a millet-seed. The skin between the individual vesicles is pale and white, and never red and swollen as in pustular small-pox.

"The slightest friction destroys the epidermis of the vesicles, and their base then appears as a moist, slightly red surface, which, on the day after the removal of the plaster, has already become dry and covered by a delicate epidermis. No scales are ever formed on this surface. In no case has M. Briquet ever seen a prominent cicatrix formed, except in one which was treated by M. Nonat, and in which there were a number of very minute cicatrices, but still widely differ-

433. Certain *complications* and several *phenomena* which occur in the course of small-pox, require particular attention.

The inflammatory affections of the mucous membranes which accompany the eruption of small-pox—the ophthalmia, coryza, laryngo tracheitis, stomatitis, &c., all require the antiphlogistic plan of treatment. "*Ubi institueretur si variolæ non adessen*" is a rule which I used at one time to take as my guide, but which now appears to me to require modification. In fact, it is found that variolous inflammatory affections do not give way to blood-letting like the inflammations that are independent of the agency of miasmata, or the inoculation of a poisonous virus; in the latter description of cases the antiphlogistic treatment ought certainly to be much less energetic than in the former.

If inflammation of the encephalon be an extremely rare complication in confluent small-pox, it is still worthy of remark that the nocturnal exacerbations are almost always accompanied by delirium and agitation. After the abstraction of a moderate quantity of blood, and the application of a number of leeches behind the ears, or to the openings of the nostrils, I have several times succeeded in allaying

ent from the deep marks of common small-pox. In this case M. Briquet doubts whether the plaster had been rightly applied.

"In order that the plasters may have the effect of modifying the eruption, they must be applied before it has become pustular; when applied later than the fifth day, they do not appear to exert any beneficial influence.

"The conversion into tubercles is more rare, and generally takes place in cases of confluent small-pox. They harden and desquamate, soon after removal of the plaster, without leaving any permanent cicatrix.

"The plaster is best applied spread upon some coarse stuff, stiff enough to support itself, and thus remain in exact contact with the skin. A little mercurial ointment is applied to the eyelids and nostrils, as the plaster cannot readily be kept upon these parts. The plaster is allowed to remain for three days in simple small-pox, and a day longer in confluent cases. No benefit is derived from a longer application, but rather the reverse, as softening of the base of the vesicles may ensue in consequence, and cicatrices be formed.

"When the plasters are allowed to remain too long, a slight erysipelas may be the consequence, but this is extremely rare. In two cases an eruption resembling measles followed the application of the plasters, but it did not appear certain that it was in consequence of them. A slight eczema is sometimes produced by the plasters, but its extent is always very limited, and it is of little consequence. In no case was any deleterious effect produced by thus modifying the eruption, but the advantages appear to be many. The inflammation that would otherwise have ensued in confluent cases was obviated, and the brain thus in all probability prevented from being affected.

"The mercury seems to be the chief agent in effecting the modification. Pressure did not produce the same effects, for the pustules were developed as fully below the adhesive plaster as upon the free surface of the skin. Neither have the plasters of lead any effect in changing the nature of the eruption; but the modification is produced by mercurial ointment spread upon the surface, equally well, if not better than by the mercurial plaster."

M. Olliffe, President of the Parisian Medical Society, read a paper before that body, recommending the mercurial topical practice. It would seem from his experience, that, although it failed as an ectrotic, when used in the pustular stage of small-pox, it still greatly modifies and ameliorates the local inflammation.

The plaster employed by these gentlemen is the *emplastre de vigo*, or the *emplastrum vigo cum mercurio* of which the following is the formula.

- R. Mercury 95 parts:
- Balsam of Storax 48:
- Common plaster 312:
- Wax, resin, and turpentine, of each 16:
- Gum ammoniac, bdellium, olibanum and myrrh, each 5:
- Saffron 3:
- Spirit of lavender 2:
- M.

these cerebral symptoms by the prolonged and repeated application of ice, or of cloths wrung out of cold water, to the head, at the same time that the feet were enveloped in warm emollient cataplasms, or that blisters were applied to the legs.

434. During convalescence from small-pox, the occurrence of furuncles, of ecthyma, and of various other forms of cutaneous inflammation, besides attention to regimen, almost always require the use of the simple emollient warm bath; this is also the period when it is frequently useful to exhibit mild purgatives, unless the state of the intestinal canal contra-indicates the practice.

The diarrhoea and cæco-colitis of convalescence are successfully met by means of *milk diet*.

Abscesses ought to be opened at as early a period as possible, and sloughs and excoriations of the sacrum, when they occur, require to be dressed with the greatest care.

435. From time immemorial, it has been the practice in Georgia, Circassia, Egypt, and Hindostan, to inoculate small-pox, in order to make it less fatal in its effects. This operation, long unknown in Europe, was performed, for the first time, in 1673, by Timoni and Pilarino,<sup>1</sup> during the prevalence of an epidemic small-pox which desolated Constantinople. The fame of the method, introduced into England by Lady Mary Wortley Montague, spread rapidly, and was generally practised all over Europe, until Jenner showed that the inoculation of the cow-pox possessed immense advantages over that of the small-pox. (a) (Vide *Vaccinia*.)

#### Historical Notices and particular Cases of the Disease.

436. Aharoun or Aaron is the first writer who mentions small-pox (622 B. C.) under the name of *djidri*, which the Latin translators have rendered by the word *variola*. The description of Rhazes<sup>2</sup> is so accurate as to leave no doubt in regard to the nature of the disease he witnessed, although it is very singular that he should have made no mention of the *contagiousness* of the affection. As to the therapeutical views of the Arabian writer, M. Eusèbe de Salle<sup>3</sup> has shown that these formed the prominent feature in his work, and that Sydenham, whatever may have been said to the contrary, had, in fact, added little to their excellence.

(a) "In inoculated small-pox the proportionate mortality is very small; but although the individuals who were submitted to the process of inoculation were safe, with comparatively little risk from present disease, and protected with considerable certainty from future attacks of small-pox, yet the mortality from this disease among the people generally was greatly increased. A large class of unprotected persons, who either could not or would not avail themselves of the benefit of inoculation, continued to exist in every country; and they became greater sufferers by the multiplied foci of contagion, caused by the separate cases of inoculation. Dr. Lettsom, by documents delivered to the committee of the House of Commons, and founded on deductions from the bills of mortality, distinctly proved that in the fifty-five years preceding the introduction of inoculation, or between 1667 and 1772, the average number of deaths occasioned by small-pox was, to the number of persons that had died of all diseases, only as seventy-two to 1,000; while in the forty-two years succeeding the practice of inoculation, the proportion had increased to eighty-five in the 1,000; and subsequently, Sir Gilbert Blane had calculated, that in the last thirty years of the past century it had increased to ninety-five in 1,000; adding, that in the year 1800 the small-pox had broken out twenty times in the Channel fleet alone." (b) See also an English translation from the Latin version, prepared by Dr. Mead and published with the works of the latter.

Many inquirers have maintained that small-pox had been seen by the Greek physicians; Willan<sup>4</sup> has strengthened this opinion by much deep and very learned research, which, however, has not satisfied my mind of its accuracy.

It is generally believed that the first eruption of small-pox occurred in Arabia. According to an Arabic manuscript in the library of Leyden, it seems to have appeared there about the 572d year of the Hegira. Transported into Egypt in 640, at the period of the conquest of this country by the Caliph Omar,<sup>5</sup> it afterwards spread in all the directions in which the Saracens carried their arms. In this way it reached Spain, Sicily, Naples, and France, from whence it was communicated to the rest of Europe and to America. There is a passage, however, in the chronicle of Marius, Bishop of Avenches,<sup>6</sup> which might lead to the belief that small-pox had appeared in Europe long before the date usually assigned to its introduction.

437. Interesting observations on *congenital* small-pox;<sup>7</sup> on *second attacks* of the disease;<sup>8</sup> on *variola sine variolis*;<sup>9</sup> on the laws of the *etiology* of small-pox;<sup>10</sup> on epidemics of *benign*,<sup>11</sup> and of *malignant* small-pox;<sup>12</sup> and of small-pox possessed of *various characters*;<sup>13</sup> on the *complication* of this disease with *peripneumonia*;<sup>14</sup> with *œdematous angina*;<sup>15</sup> with *pseudomembranous angina*;<sup>16</sup> with *croup*;<sup>17</sup> with *pseudomembranous bronchitis*;<sup>18</sup> with the *granular eruption of the intestinal canal*;<sup>19</sup> with *purpura*;<sup>20</sup> &c. Various remarks have also been made on the *secondary fever*,<sup>21</sup> and on diseases *consecutive* to small-pox.<sup>22</sup>

For information on the structure of the pustules, the work of Cotugno<sup>23</sup> may be consulted (he has given a good account of the *small white filaments* which traverse small-pox pustules), and the lectures of M. Chevalier,<sup>24</sup> who has demonstrated the existence of a pseudo-membranous substance in the umbilicated pustules. M. Deslandes has erroneously ascribed the pits in the centres to the pores of the skin; another writer,<sup>25</sup> upon no better grounds, indicated the *sebaceous follicles* as the seat of the disease. Even the *crusts*<sup>26</sup> of small-pox have repeatedly been made the subject of chemical analysis. Remarks have been published on the treatment of small-pox, by *excluding the light*,<sup>27</sup> by *puncturing*,<sup>28</sup> and by *compressing*<sup>29</sup> the pustules, and on the *ectrotic*, or method of treatment by cauteriza-

tion.<sup>1</sup> Calamine<sup>2</sup> and chlorate of lime<sup>3</sup> have been recommended to prevent the occurrence of cicatrices; lastly, copious venesection has been recommended to cause the *miscarriage* of the pustules.<sup>4</sup> The subject of *inoculation* of small-pox has given occasion to many works.<sup>5</sup> This operation by means of *punctures* has been performed on animals in the hope of producing the small-pox pustules, but in vain.<sup>6</sup> Dr. Sunderland<sup>7</sup> having lately announced that he had succeeded in engendering vaccinia in kine, by clothing them with a coverlid taken from the bed of a small-pox patient, the experiment was repeated by Dr. Numan of Utrecht,<sup>8</sup> who informs us that no eruption occurred either on the teats or udder, but that a few variculous pustules were developed on the bodies of the animals. These experiments require to be repeated.

To conclude, Dr. Gregory has proposed to divide legitimate variola into five varieties.<sup>9</sup>

CASE LXIV.—*Confluent small-pox of the face; cerebral congestion treated by means of ice; gastro-intestinal irritation; boils.* Et. Tronchet entered La Pitié on the 24th of February, 1826. Eight days previously he had been attacked with sickness and vomiting, headache and fever, which for the last three days had kept him confined to his bed. Last night, after several attempts to vomit, and a noise of ringing in the ears, an eruption was remarked upon the skin. A considerable number of red raised spots, which under the finger feel like small rounded grains, are scattered over the face, and also, but more sparingly, over the trunk and limbs. These spots become pale on pressure, but still continue elevated above the surface; some of those of the face show a transparent point at the summit; the skin is hot and perspiring; the tongue white, moist and very red on the edges; the patient is thirsty, complains of epigastric pain, and the belly seems tumid; he has a dry cough, which increases the pain of the abdomen; the pulse is full and frequent (*fifteen leeches to the epigastrium; mucilaginous drink; low diet*). 26th.—No sleep through the night; singing in the ears; chills succeeded by copious perspirations; the leech bites continue to bleed; the spots of the face are larger and more numerous; the tops of the majority of them look white; the skin preserves its natural colour in the intervals between several of them, but it is red in those places where the eruption is clustered and confluent. The eruption is greatly increased since yesterday on the forearms, wrists, and eyelids. Tongue of a yellowish white; pain and heat of the pharynx; constipation; cough without alteration of voice; heaviness of head, and tardy answers to questions (*mucilaginous drinks*). 27th.—Sweating; delirium during the preceding night. The pustules are larger, less prominent, and full of a sero-purulent fluid; several show a small depressed point in the centre. The conjunctiva is injected and moist, the nose swelled and painful; the nostrils seem obstructed. The patient complains of shooting pains in the head, of inability to fix his eye steadily on any thing, and of weakness in the senses of sight and hearing (*thirty-two leeches to the fore part of the neck, mucilaginous drinks*). 28th.—The patient had

passed the night in a delirious state, and had sprung several times out of his bed. The face is red and swollen, and the pustules are almost all coherent. Other symptoms continue much the same; pulse frequent (*ice to the head*). The confusion of head went off while the ice remained applied; but as it subsequently returned, the ice was renewed and the patient passed a quiet night. March 1st.—The face more swelled than ever; several pustules discovered on the sides of the tongue, which is white and moist. General symptoms continue as before, but the pulse is no longer quick, and there is some headache (*demulcent drink with honey; ice to the head, emollient glyster*). The whole of the cerebral symptoms are much improved since the ice was applied, and the patient has not again been delirious. 2d.—The pustules of the face are nearly in the same state as yesterday; the features are swelled, but the colour of the skin is not so deep as it is usually in confluent small-pox. A series of small pustules beset the free edges of the eyelids. The tongue is dry in the centre, moist on the edges; the patient is thirsty; he swallows with greater ease, and has had a natural evacuation from the bowels; the pulse is quick; the voice clear and sonorous (*demulcent drink; lavement*). In the evening, some degree of deafness, singing in the ears, and headache; a fresh application of ice was followed by sleep. 3d.—The eyelids are closed and bathed in a serous and puriform fluid; several pustules have begun to dry up. The tongue is painful and swelled; thirst; abdomen tumid; expulsion of flatus by the mouth; colic; pain in the pharynx, voice natural; pulse frequent. The ice was not applied during the day; the headache returned, and was followed by a sort of stupefaction. 4th.—The desiccation of the pustules is very far advanced on the lips, chin, and alæ of the nose; on the limbs and chest the eruption is still suppurating, the pustules being large, slightly flattened, and opalescent in colour; a very few of them only are punctuated and depressed in the centre. Ecchymoses have taken place spontaneously over the clavicles. Continued perspiration, tongue dry and brown, considerable thirst (*demulcent drink; ten leeches to the front part of the neck; ice to the head*). The patient slept during the night. 5th.—Swelling of the face subsided; the whole of the skin is hot, and painful to the slightest touch. Tongue moist; deglutition still more easy; thirst; constipation; voice sonorous; pulse by no means quick; slight headache (*honey drink; ice to the head for half an hour*). The patient passed a quiet night. 6th.—Large brown incrustations on the chin, yellow or brownish scabs on the cheeks, separated by several pustules, the development and suppuration of which occurred at a late period. The pustules of the forehead and temples are not yet desiccated. The patient complains of intense pruritus and painful shootings in the face; on the breast the greater number of the pustules are still full of pus; on the limbs they are generally umbilicated, and have a silvery appearance; on the forearms the centres of a few of them begin to grow yellow; many clusters are shrunk and wrinkled. Tongue moist and white; considerable thirst; some sensations of hunger; natural evacuations from the bowels. Headache in the evening relieved by the application of ice for three-quarters of an hour; sleep during the night. 7th.—The pustules of the back part of the neck flattened and brown in their centres. On the wrists they look silvery. Proceeding from the circumference towards the centre, the greater number are surrounded successively with a pale rosy and linear areola, a white circle, a second slightly brown circle, lastly a circle of yellowish-white, the centre of which is depressed. The whole face seems covered with one large incrustation, forming a kind of party-coloured mask, of various shades of brown, yellow, and green. Several purulent bullæ are observed on the wrists and left forefinger. Tongue and digestive apparatus are in the same state as before. 8th. Several pieces of incrustation are detached over the right cheek, and the skin they covered appears ulcerated in different places. On the left cheek the incrustations seem ready to fall; on the forehead they are more adherent. The pustules of the chest shrink and dry up apace, as do those of the forearms also. The greater number of those situated on the knees and legs are still full of pus; all the others are flaccid (*mucilaginous lemonade; soup*). 10th of March.—The desquamation continue in the face; the skin, where freed from the incrustation, presents several chaps from which a few drops of blood have distilled. The pustules are drying on the fingers (*panada; broth*;

1. Superficial variola in which the eruption only attacks the skin.

2. Cellular variola in which the variolous action extends to the subcutaneous cellular membrane, and is followed by abscesses.

3. Laryngeal variola in which the inflammation attacks the larynx and trachea.

4. Nervous variola.

5. The fifth variety is owing to an altered state of the blood, and is characterized by petechiæ and passive hemorrhage.

*mucilaginous lemonade*). 11th.—Desquamation continues. A boil has been evolved on the right side of the chest. Tongue clean; appetite; sleep; pulse weak and slow (*lemonade as before, the eighth hospital allowance, without any wine; lavement*). A second boil has appeared on the sacral region; the patient was up for four hours during the day. 13th.—Itching and tingling over the whole of the integuments; mouth clammy, belly somewhat tense. 14th.—Same state (*the half portion without wine*). 15th.—Mouth dry, thirst, pains in the bowels (*mucilaginous lemonade, beef-tea*). The irritable state of the alimentary canal which had formed one of the features in the case during the whole of its course, and was attended with the disengagement of large quantities of flatus, still continued for some time longer, requiring particular attention to diet and regimen; but the patient finally left the hospital perfectly well on the 20th of March.

CASE LXV.—*Congenital ichthyosis; confluent small-pox, the pustules of which seemed to be impeded in their development by the unusual thickness of the epidermis; laryngo-tracheitis*.—J. Porte, aged twenty-three, the subject of a congenital ichthyosis, entered La Pitié on the 10th of March, 1826. He had complained of headache, and great pain in the loins on getting up in the morning of the 11th; next day, he vomited two or three times. On Monday, the 13th, an eruption of small-pox appeared; a great number of red prominent elevations were scattered over the whole surface of the body. The skin of the face looked mealy, that of the thorax was uneven, rough to the touch, and traversed by slight furrows and prominent lines which crossed each other irregularly. On the sides of the chest and upper parts of the abdomen the cuticle was coming off in scaly layers. On the other parts of the belly it was of a mixed gray, and light greenish colour, disposed in perpendicular bands about three lines in breadth, separated from each other by slight furrows, the delicate cuticle of which formed a strong contrast with the thickness of that of the bands. On the back, arms, and shoulders, the cuticle was hard and thick, and was detached in scales. The forearms and thighs were affected with a slight furfureous desquamation. The patient informed us that his mother, his maternal uncle, and one of his brothers were affected in the same way. On the 15th, the furfureous skin of the face was covered with pustules so closely crowded together, that there was scarcely a point unoccupied; they were also confluent on the fore part of the neck, and were extremely numerous on the chest and limbs. The tongue is white, covered with nascent pustules; there is headache; answers to questions are delivered slowly; noises are complained of in the ears; the pulse is frequent and unequal; deglutition is difficult; pain is felt in the throat and pharynx; and fits of sneezing occur at intervals. 16th.—Sleeplessness, and raving during the night (the patient confined with the strait waistcoat); great dryness of the skin; pustules of a dull white colour, tongue yellowish, pain and very evident heat in the pharynx; swallowing performed with great difficulty; hard and distressing cough; pulse strong and frequent. 17th.—The delirium last night was again violent and attended with extreme restlessness.

The pustules on the face are confluent and umbilicated, *but they scarcely rise above the level of the skin*. On this region as well as upon several others, they seemed to be impeded in their evolution by the morbid and thickened state of the epidermis. The redness and swelling of the face are less remarkable than in small-pox developed in healthy integuments. On the abdomen and lower extremities, the eruption is less marked. The conjunctivæ are injected and the seat of an unpleasant sensation of smarting; the bowels have been locked up for a week, but the abdomen is nowise painful; cough very distressing. (*Diluents, sixty leeches to the lower part of the neck*.) 18th.—Rather better; the pustules of the face are stationary; the features are not swelled; cough guttural and frequent; nostrils dry and plugged with mucus; conjunctivæ injected; bowels opened; deglutition easier (*gum-water*). 19th.—The pustules of the face are generally shrunk and shriveled; those of the legs are small, white and but slightly raised above the surface; some of them are even shrunk and of a brownish colour; the restlessness and delirium were less in degree last night; slight headache; frequent cough; pain in the windpipe; voice altered and hissing; guttural rattle during expiration; tongue brown; deglutition followed by cough; pulse excessively quick. 20th.—Several brown scabs have formed on the forehead and at the root of

the nose. On its alæ and bridge, the cuticle is detached over a space of an inch in diameter, leaving the dermis exposed, the surface of which appears uniform and of a brownish-red colour. No farther traces of pustules are discoverable on the cheeks; on the other parts of the face they are coherent, flattened, and form large white and slightly prominent patches. On the trunk the pustules are flattened, white, very slightly raised above the surface; several of them are dry upon their summits. On the lower parts of the legs, large epidermic scales appear ready to fall off; the skin is of a pale red in the greater number of the intervals between the pustules, and white in the rest. The eyelids are flaccid, lips half open, tongue brown, covered with yellowish pustules upon the edges; abdomen soft, epigastrium painful; deglutition followed by cough; sonorous rattle at the inferior lateral part of the left lung, respiration noisy, cough troublesome, voice hoarse and weak, pulse small and contracted, death at noon.

*Examination of the body*.—The skin of the face is but little injected; that of the neck, legs, posterior parts of the thighs and buttocks is of a deeper red than usual; and the morbid coloration has not the livid tint observed in dead bodies generally. All the pustules which have not been injured are umbilicated, even in those situations where the ichthyosis is most remarkable; but they are generally smaller than the pustules at this period of small-pox. *Head, abdomen, thorax*.—The subserous cellular tissue of the arachnoid membrane covering the right lobe of the brain is injected; the same structure of the left side also exhibits several red patches; the base of the brain does not appear more vascular than usual; the white substance of the interior is slightly sandy (*sablée*) and there is a little serum in the ventricles; the other parts as well as the cerebrum are natural. The conjunctiva of the eye is not inflamed; but the membrane of the nasal fossæ is of a vivid red, and overlaid with thick yellow mucus. This membrane can be detached with the greatest facility from the bone beneath; the arch of the palate is covered with a great quantity of gray matter, the remains of the pustules with which it has been beset. The pendulous veil of the palate and its pillars are of a livid red. The tongue is covered with a thick, white matter; its papillæ are extremely prominent; its centre is livid and its muscles are injected. The whole of the pharynx is covered with a yellowish exudation; the natural colour of the œsophagus forms a strong contrast with the inflammatory tint of the pharynx. The stomach is distended by matters tinged with bile. The inferior curve presents a punctuated red appearance over an extent of about three inches every way. The termination of the small intestines, and the cæcum in particular, are not inflamed, and show no traces of pustules. A large quantity of bilious-looking stuff is contained in the different portions of the intestinal canal. The liver is large, and the spleen looks gorged with blood. The lining membrane of the larynx, trachea and bronchia is beset with small white spots crowded together in different degrees. These were not pustules, in the proper sense of the word, for small spots of a white colour, circular in shape, flattened on their surface and from one to two lines in diameter, were all that were detected. Some of them were no larger than a millet-seed, others in their form and dimensions resembled the clusters of confluent small-pox as they appear in children; others again were of the most irregular and dissimilar shapes, and evidently resulted from the agglomeration of several of the patches. The membrane over which these spots were dispersed, was in several regions of a livid red colour, and the various changes of which it formed the subject, gave it altogether a marbled or variegated appearance. The redness declined gradually from above downwards, and became less and less appreciable as the minuter subdivisions of the bronchi were attained. There was no trace of pustules beyond the bifurcation of the trachea, although the mucous membrane of the air-tubes generally was highly inflamed. The lungs were gorged in their posterior parts; the bronchial glands, situated near the first division of the bronchi, were black; the heart was sound, the right auricle alone presenting a livid tint, probably communicated by the great quantity of blood distending its cavity. The aorta and crural arteries contained little blood, but presented a great number of red stains of various shades of colour, which did not extend beyond their inner membrane.

The muscles were of a brownish-red hue; the sheaths of the exterior tendons of the left foot were full of yellowish pus; the articulations were healthy.

The red colour of the inner membrane of the arteries which I was formerly, 1826, inclined to attribute to inflammation, appears to me now to be owing rather to the *imbibition* of blood, which would seem to be favoured in some patients who die of small-pox by a peculiar state of this fluid. (a)

(a) I introduce here the three following cases which occurred in my hospital practice, and which are detailed in the passages already referred to in *N. Am. Med. Journ.* They will serve to show the appearance of the gastro-pulmonary mucous membranes in the several stages of the disease.

"I.—Ann Collins, white, aged 18 years, unprotected, became sick on Tuesday evening March 23, 1824, and was taken to the Almshouse, as one having the measles on Wednesday. On Thursday evening, some eruption was visible; on Saturday evening, March 27th, admitted.

"28th.—Visited. Face covered with a red, flat, dry eruption, particularly on the cheeks; small and vesicular on the chin and around the mouth. On the arms, it has the appearance of measles; on the hands, it is of a deep scarlet, with central vesicular elevations; on the legs is slight; tongue loaded and yellow, except at the borders, which are clean; pulse natural; complains much of pain in the back and sickness of stomach.

"30th.—Eruption covering the face, vesicular on a deep red ground with some tumefaction; rising vesicular on the limbs with scarlet bases. Tongue smooth and shining anteriorly, and with vesicles on it. Throat sore. Salivation. Pulse small and feeble. Has had menorrhagia since her admission into the hospital.

"31st.—The menorrhagia continues. Had last night epistaxis. Pulse small and slow. Tongue furred and red. Eruption confluent with indented and dark centres. Surface white and dry. Skin between red and inflamed. Very slight eruption on legs, and none on feet.

"April 1st.—Menorrhagia continues. Pulse small and labouring. Respiration laborious and hurried. Face swelled. Surface smooth, with white spots to represent the pustules. On breast and arms the eruption is in confluent patches which are nearly continuous—some pustules flat and indented, others smooth, with appearance of radii, and some more elevated forming blebs. Skin of the feet cold, and blue in spots; no elevated eruption on lower extremities. Tongue furred and yellowish. Throat sore. Eruption very copious on body, generally with blebs.

"*Vesperi*; pulse hardly perceptible. Anxiety and distress great. Dead at 10 P. M.

"*Examination* April 2d, in the afternoon.—On opening the thorax, the lungs and heart were found of the natural appearance and size. The larynx and trachea being divided, exhibited all the way down to the lungs an injected surface with whitish irregular spots, having nearly the same appearance as the flat smooth eruption on the face: in parts it was more evidently pointed, and showed by the aid of the microscope, a pustular appearance. In the lungs, the inner surface was still darker. The root of the tongue was covered with large and rather hard papillæ, with open summits. The œsophagus was smooth and white. The stomach near the cardia injected, and of a brownish-red in spots: the remaining portion white, presenting no diseased appearance. The spleen was very large and covered with copious miliary points. The omentum, to appearance gangrened, was dark, and altered in texture. The peritoneum, especially in the pelvis, was injected and inflamed, being of a semi-opaque dark colour. The uterus, small and firm, contained some bloody mucus in its cavity.

"II.—Joseph Foster, white, aged 22 years, unprotected, became sick on Monday evening 8th of March. The eruption began to show itself on Wednesday morning, 10th.

"12th.—Admitted and visited. Face covered with a red, dry, tubercular eruption, with some few yellow pustules. Same on arms, but no pustular appearance; partly tuberculous, partly vesicular. More sparse and scattered on breast and legs: none on feet. Slight cough. Tongue white, clammy, and loaded in middle—red at borders. Pulse rather frequent.

"14th.—Face covered with a pustulo-vesicular eruption with

whitish summits, red and inflamed bases. Skin between of same colour. Eruption dry and hard; very red, copious on limbs; less so on trunk. Tongue moist and less loaded. Pulse regular.

"15th.—No fever. Face of a deep red colour; eruption rising from it rather flat, irregular in figure and white at summits. Eyes inflamed. On limbs the eruption is red at base, vesicular in body and summit: on trunk in clusters. Tongue yellowish and rather furred. No complaint made; rests easy; sleeps well.

"16th.—No fever; tongue moist and a little loaded. Pustules nearly white. Some yellow, and beginning to dry on summits. Skin between still of a deep red. Eruption filling on limbs and trunk.

"17th.—Pulse strong and frequent; skin hot; tongue moist and loaded. Pustules scabbing on face. Not yet entirely filled on limbs, where they are in clusters with inflamed bases.

"18th.—Pustules full and matured on limbs. Running into each other in places. Tongue dry, brown, and furred in centre, yellow and loaded at sides. Pulse quick and frequent. Lies easy.

"19th.—Blebs formed on arms; pustules running into each other, beginning to shrink; matter oozing out. Tongue covered with a dark crust. Pulse quick and frequent. Erysipelas of eyelids and ophthalmia. Throat sore.

"20th.—Blebs larger and more numerous on hands and arms; purulent matter oozing out from some of the pustules. Face nearly scabbed over. Some small white pustules formed on the eyelids. Pulse frequent and vibrating. Tongue as yesterday. Gums tender.

"21st.—Pulse weaker. Desquamation going on; pustules shrunk and drying on limbs. Tongue as yesterday.

"22d.—Matter much absorbed on limbs, leaving a shrunk cuticle. Face covered with a brown and yellow scab and scurf. Tongue black and furred; clear at apex.

"23d.—Some erysipelatous inflammation of the skin; pustules all nearly disappeared from arms, trunk and thighs; some few, white and soft remain scattered over breast. Pulse frequent. Tongue black and incrustated.

"24th.—Was brought into town from Bush Hill.

"30th.—Desquamation nearly complete. Low frequent pulse. Respiration slow and laboured. Tongue incrustated.

"April 2d.—Dead at 10 A. M.

"Calomel had been freely given to this man in the earlier stage of his disease: and during the last week, spts. terebinth. and nutritive farinaceous food.

"*Examination*.—The pericardium, of a greenish colour, and its capillaries finely injected, was full of yellow serum. The lining membrane of the larynx and trachea was of a greenish-yellow colour throughout, and in the spaces between the cartilages, ulcerated and disorganized in several spots. Beneath the membrane was a venous injection. About the bifurcation it was injected; and in the ramifications of the trachea were seen several inflamed, and in places abraded and disorganized spots. A chocolate-coloured liquor with a sediment filled the bronchiæ and the larger tracheal subdivisions.

"The œsophagus was sound. The stomach showed clusters of bright red and brownish-red spots, in stellated and other irregular figures extending along the smaller curvature. The duodenum, at its commencement and in its course, presented similar clusters. The rest of the intestine was healthy. The brain was to appearance in a natural state.

"III.—Peter Johnson, black man, aged 38 years, unprotected, was taken sick on Monday, 29th March, in Sandy Hook. Eruption of small-pox appeared. April 3d, Saturday morning. Admitted same day.

"4th.—Eruption copious on face; papular and of irregular figure. Eyes suffused and red. On arms, same appearance as on face, but less tuberculous. On breast and body, eruption small and pointed; beginning to show on legs. Throat sore. Tongue yellow and loaded at sides; red in centre. Pulse full, equal, and rather frequent. Cough.

"5th.—Much anxiety and moaning. Eruption rough and tuberculous on face. On arms, it is in parts papillary and pointed, and in parts flat with indented centres. Pulse slow and equal.

"6th.—Eruption hard and tuberculous on face and arms; small and pointed on breast. Pulse slow; throat less sore; mind wandering. Is sitting up in bed, dressed. Tongue moist and yellow.

"7th.—Delirious through the preceding night; is now dozing. Eruption same as yesterday. Not so thick on legs, but hard and tuberculous.

"8th.—Tongue black and incrustated. Throat very sore. Eruption hard and flat. Pulse active.

"9th.—In a comatose state. Pulse slow. Skin cool.

"10th.—In the same condition. Drawn down in the bed, the thighs flexed on the abdomen, and lies on his side.

"11th.—Dead at six A. M.

"*Examination.*—The upper surface of the tongue of a brownish-yellow, full of holes and rough. At the posterior part, in place of the larger papillæ, were ulcers and cavities. The posterior nares and pharynx were covered with holes, formed by ulceration, and of a brownish hue, adjoining injected and apparent pustular parts. Tonsils ulcerated, and their investing membrane mostly destroyed. The œsophagus immediately below the glottis, smooth and sound. Yellowish matter flowing from the glottis. On opening the larynx, it was found half filled with a viscid light olive-coloured fluid; on removing which, the whole lining membrane, down to the bifurcation of the trachea, was found covered with clusters of ulcerated pustules of a yellow colour, with the intervening spaces of a brownish-red, highly injected, and destitute of its natural smooth, shining appearance. The internal surface of the glottis and epiglottis was in a similar but less marked state as the larynx and trachea. The pustular surface extends to the minute ramifications of the bronchiæ, and their cells beyond were highly injected.

"On opening the abdomen, the omentum was found dark and shrunk. Stomach contracted. Intestines distended, shining, and very vascular, with capillary injection when viewed externally. The peritoneal covering of the stomach showed a similarly injected appearance.

"The stomach being opened, displayed at its upper curvature, spaces studded with spots of a deep red or purple; apparently effusions surrounded by a vascular net-work. Same appearance towards the pyloric orifice, and in places on the duodenum, which together with the jejunum, particularly the latter, is of a dark leaden colour, and injected.

"The diaphragm on its upper surface, highly injected, as was also the pleura lining the thorax. The pericardium healthy.

"The brain was not, unfortunately, examined."

The following observations and tables by Dr. Gregory, (*Lectures on the Eruptive Fevers*), as noticed in the *Medico-Chirurgical Review*, January, 1844, will form an appropriate conclusion of the subject:

"Upon an average of years, 350,000 persons die annually throughout England and Wales; and 46,000 in the metropolis. The mortality by the four great epidemic maladies (small-pox, measles, scarlatina, and whooping-cough), is very nearly 40,000 in England and Wales, and about 5000 in the metropolis, averaging one in nine of the total mortality, or eleven per cent. This is a very large proportion. That four diseases only should absorb one-ninth of the total mortality of this, and probably of all other countries, may well excite our surprise.

"Table, exhibiting the Amount of Epidemic Mortality in England and Wales, during the years 1838, 1839, 1840.

	Year 1838.	Year 1839.	Year 1840.
Small-pox - - - - -	16,268	9,131	10,434
Measles - - - - -	6,514	10,937	9,326
Scarlet Fever - - - - -	5,802	10,325	19,816
Total Mortality by the Exanthemata -	28,584	30,393	39,576
Whooping-cough - - - - -	9,107	8,165	6,132
Total of Epidemic Mortality - - -	37,691	38,558	45,708
Total Mortality throughout England and Wales - - - - -	342,529	338,979	359,561

"This table shows that every year is distinguished by some master epidemic. In 1838, small-pox was the ruling epidemic throughout England. In 1839, measles and scarlatina struggled for the mastery.

## VARICELLÆ (VARIOLÆ SPURIE).

Vocab. *Varicella*.

438. I designate under the collective title *varicellæ* or *modified small-pox*, several contagious inflammations, pustular, vesicular or papular in their nature, unaccompanied with secondary fever, arising from, and having the power of transmitting the variolous contagion, and running their course within the space of one or two weeks.

The word *varicella* has long been familiarly employed in the language of medicine to signify a modified or spurious kind of small-pox; this consideration has determined me to make use of the term here, in the same general and comprehensive acceptation.

The number of varieties composing this group is not yet precisely ascertained. I have restricted myself to a description of the following: 1st. *Pustular varicella* (the *varioloïd* of some recent writers), distinguished according to the form of its pustules into the *umbilicated*, the *globose* and the *conoidal*. 2d. *Papular varicella*. 3d. *Vesicular varicella* or chicken-pox, and 4th. *Varicellar fever*.

439. A smaller number of species than those now enumerated were recognized in earlier times. Rhazes<sup>1</sup> speaks of a *false variola* which does not give immunity from small-pox at a subsequent period. Guido or Vidius<sup>2</sup> describes this false variola under the title of *crystalli*. Sennertus<sup>3</sup> admits three varieties of spurious variola; Sydenham,<sup>4</sup> whilst giving an account of a variolous epidemic, mentions a false variola which does not protect from a second attack; Morton<sup>5</sup> borrowed from the vulgar the denomination of *chicken-pox* to designate a disease of the same description. In a word, all the writers anterior to the period when inoculation was generally practised, speak of the occurrence of spurious variola which does not secure the individual affected against a future attack of the legitimate small-pox; and whilst some of them regard it as a very slight and benign variola, others treat of it as a distinct and specific disease. From the year 1772, the period at which small-pox inoculation was first practised in England, till the introduction of vaccine inoculation, the same opinions were constantly entertained. Hoffmann,<sup>6</sup> again, associated the whole of these eruptions under the single head of *variola spuria*. Van Swieten<sup>7</sup> recognized three species (steen-pocken, water-pocken, wind-pocken); Heberden<sup>8</sup> and Cullen<sup>9</sup> held chicken-pox to be the product of a pecu-

In 1840, scarlet fever was so general and so fatal that the mortality by it exceeded by one-fifth the ravages of small-pox during an epidemic season (1838), and more than doubled the mortality by that disease in 1839.

"The following table, exhibiting the amount of epidemic mortality in the metropolis during a period of five years, shows that the same general principle applies to town and country, but is less manifest in the smaller population:—

"Table, showing the Amount of Epidemic Mortality in London, during Five Years—1838 to 1842.

	Year 1838.	Year 1839.	Year 1840.	Year 1841.	Year 1842.
Small-pox - - - - -	3,817	634	1,235	1,053	360
Measles - - - - -	588	2,036	1,132	973	1,292
Scarlet Fever - - - - -	1,524	2,499	1,954	663	1,224
Total Mortality by the Exanthemata - - -	5,929	5,169	4,321	2,689	2,876
Whooping-cough - - - - -	2,083	1,161	1,069	2,278	1,603
Total of Epidemic Mortality	8,012	6,330	5,390	4,967	4,479
Total Mortality throughout London - - - - -	52,698	45,441	46,281	45,284	45,272"

liar specific cause, whilst Sauvages<sup>1</sup> and Burserius<sup>2</sup> describe the disease as a variety of small-pox. Lastly, since the practice of vaccination became general, a remarkable modification of small-pox has often been observed, which Dr. Cross,<sup>3</sup> of Norwich, has regarded as a species of varicella, (*varicella cellulosa*), and I have treated of here under the title of *umbilicated pustular varicella*, but which has been separated from this class of complaints by Dr. Eichhorn<sup>4</sup> and others under the name of *varioid*.

However different these opinions may appear, it is still an assured fact, that ever since the small-pox was observed as a peculiar disease, a certain number of *spurious* cases, as they have been entitled, have occurred, which did not confer security against an ulterior attack of the more formidable malady. It is also established that many of these eruptions are characterized, like legitimate small-pox, by pustules or pseudo-membranous vesicles, whilst others show themselves under the form of transparent vesicles or of papulæ. Now if they be all of the same essential nature, and produced by the same contagious influence, as I conceive it is satisfactorily demonstrated that they are, the different elementary forms of these varieties will be found adequate to distinguish them from each other, without there being any necessity felt to resort to a new denomination for this purpose. Several modern pathologists, however, have especially designated the *pustular varicella*,—that variety of the disease in which the pustules are umbilicated like those of small-pox, under the name of *varioid*. But other observers, with Dr. John Thomson at their head, who first made use of the title, have employed the term *varioid diseases* as designating all the forms of eruption to which the contagion of small-pox could give rise, chicken-pox included among the number. Lastly, others, among whom we have to reckon Dr. Eichhorn, have detached legitimate small-pox and chicken-pox from this group, and have restricted the application of the name *varioid* to those variolous eruptions which presented umbilicated pustules in larger or smaller numbers, but were in every case unaccompanied by secondary fever.

With so many different meanings attached to the word *varioid*, therefore, and with a feeling of disinclination arbitrarily to detach the *pustular varicella* from those that show themselves with other and different features, I find myself obliged to reject the term entirely, which, indeed, is nowise necessary to me, inasmuch as I believe that even the purely *vesicular* form of varicella is produced by the contagion of small-pox.

The treatment of the varicellæ is in general the same as that of the distinct and benign form of small-pox. § 425.

#### *Pustular Varicella* (the *Varioid* of modern authors).

440. The red raised spots by which *pustular varicella* makes its appearance, are often pretty large and firm under the finger. They are surrounded by an irregular pale red areola, which is not uniform in its depth of colour, but is, as it were, sprinkled over with redder points or patches, usually of small dimensions, but occasionally very extensive, particularly in those situations where the eruption is to be confluent, or in their immediate vicinity.

On the second day of the eruption the summits of the spots are detached from the corion, the interspace being occupied by a minute globule of transparent fluid. These vesicles increase slowly in size, becoming gradually more and more opalescent, and at last appearing quite white. The pustules are now firm under the finger and scarcely discharge any thing if punctured. The opacity and white colour of some of the pustules appear to depend almost entirely on the presence of a sero-purulent matter which they contain; they thus form a kind of link of transition from the vesicular to the pustular form of cutaneous inflammation. More generally, however, the opacity in question is owing to another cause, namely, the presence of a disc of pseudo-membranous exudation in their interior (*umbilicated pustular varicella*) closely applied and adherent to the inner surface of the epidermis; although it must not be forgotten that a thick, yellowish and semi-transparent matter like jelly can be squeezed out of the interiors of

the very large or confluent pustules, especially when they are somewhat far advanced. The same circumstance is also very well seen in some globular pustules (*globose pustular varicella*), which, after the very first days of their existence, become opalescent, and at length opaque and white. A transparent vesicular circle is perceived to be formed around the pseudo-membranous disc, evidently by the detachment and serous elevation of the neighbouring cuticle. At a later period this circle disappears, the fluid it contains becoming milky. The false membrane is occasionally very thick; but in general it is less so than in small-pox; it always adheres to the cuticle, with which it might be confounded without due attention. It has a cellular aspect, but does not present the cupped appearance observed in small-pox except in the umbilicated pustules, which approach those of true small-pox more than the generality. The false membrane of the interior of the pustules also adheres to the surface of the corion; if they be laid open, a soft and whitish matter is found covering the surface of the papillæ. The epidermic conduits of the hairs which happen to pass through the pustules, look larger and whiter than usual. It appears consequently that the form and colour of the pustules of varicella depend on the extent and thickness of the false membrane deposited, and on the quantity of serum effused within them.

441. The red elevated spots of the corion continue, and even occasionally increase after the formation of the pustules. In those of a large size, and especially in such as are confluent, (in which, after having removed the cuticle, a better view can be obtained of the surface of the corion, of the false membrane and of the gelatinous-like matter contained in the pustules,) we observe in the point corresponding to the centre of each primary pustule, a small *eminence* or nipple-like projection, white on the top, red in the circumference, and surrounded by an intense degree of redness and some slight sanguineous effusion. At a subsequent period this little swelling of the corion subsides, but it is at times still visible, after the fall of the incrustations that are subsequently produced under the form of a lenticular eminence of a pink colour, surrounded by a white border which is due to the torn edge of the epidermis.

442. The *areola*, or red ring, which surrounds varicellar spots, broad at first, faint and irregular afterwards, becomes at length more circumscribed and of a deeper hue; when these spots are clustered together, or arranged in bands, they occasionally bear some resemblance to herpes. The intense red colour of the areola continues till the beginning of the period of desiccation, when it decreases considerably, and assumes a brownish hue which disappears in the course of time.

It is rare that true suppuration is set up in the pustules of varicella; they consequently almost never leave cicatrices.

#### 1. UMBILICATED PUSTULAR VARICELLA.

Vocab. *Varioid*, *Modified Small-pox*, *Cellular Varicella*.

443. This variety, which in fact differs from distinct small-pox in nothing but in the non-occurrence of the *secondary fever*, has been studied with particular attention in these latter days. It is most frequently observed under rather remarkable circumstances: 1st, in individuals who have had small-pox naturally or by inoculation, or who have been vaccinated and have been accidentally again exposed to the contagion of variola; it occurs, also, in those who have been a second time inoculated with the variolous virus; lastly, in some rare cases, it appears in individuals who have never been vaccinated, and have never had small-pox; it would seem farther to have been occasionally communicated by inoculation.

444. *Symptoms*.—The eruption may be slight or confluent; it is occasionally preceded by roseolous blotches disseminated over the surface of the body. In other respects the precursory symptoms of the *umbilicated pustular varicella* are extremely similar to those of the distinct small-pox. Generally of extreme mildness, these are, however, occasionally very alarming, and are attended with pain of the epigastrium, vomiting, delirium, &c. Their progress and intensity are by no means in relation to the extent of the cutaneous

<sup>4</sup> Eichhorn. Op. cit., vide varioid.

inflammation which is to succeed them: to a very smart attack of fever, extreme restlessness, and much delirium, we often see a very slight eruption succeed, the appearance of which is followed by the complete cessation of every serious and alarming symptom.

On the third or fourth day, dating from the invasion, the eruption shows itself upon the trunk, face and extremities, under the form of small red spots similar to large flea bites, which soon become hard, elevated, and, as it were, papular, though all do not follow the same course. Some disappear without becoming pustular, and others become vesicular or pustular in the course of eight and forty hours. On the morrow after the appearance of the eruption, the red spots are more prominent and acuminate, and contain a serous fluid in their apices. On the third or fourth day of the eruption the larger number are found to have acquired the *flattened* form, which the pustules of legitimate variola only present at a considerably later period. Thus arrived at their *height*, the pustules of this variety of varicella, flattened and oval-shaped, generally present a depressed point in the centre, and are surrounded by a narrow pale red circle. They are mostly from one to two lines in diameter. When compressed they resist under the fingers like bees-wax, and when they are punctured in one or two places with the point of a lancet, the plastic and nearly solid matter they contain does not escape. Their colour, at first of a pale pink, becomes of a dull white on the fifth and sixth day. On the seventh day of the eruption the greater number of the pustules have not yet changed their shapes; others, and especially such as are the most remarkable, are by this time occupied in the centre by a small brown or yellowish point of incrustation, which makes them appear still more umbilicated. Whatever may have been the degree of intensity of the eruption, no *secondary*, or as it is entitled, *suppurative fever*, which, in legitimate small-pox, is set up at this stage, ever appears. On the eighth day of the eruption, (thirteenth or fourteenth of the disease,) the pustules have shrunk, and are replaced by scabs of a yellowish-brown colour, laminated in their texture, sub-epidermic and lenticular; on the face, indeed, the greater number of the crusts are often detached before this time.

After the removal of the crusts, a few circular and depressed cicatrices, and a great many small or red livid spots are discovered upon the skin; these may continue very conspicuous, even two months after the invasion of the disease.

Inflammatory affections of the larynx and trachea, so frequent in confluent small-pox, are seldom observed in the umbilicated pustular varicella; but the skin, and especially that of the face, may be very much injected, erysipelatous in appearance, and the seat of severe tensive pain. Pustules are now and then observed thrown out on the mucous membrane of the mouth and on that of the genital organs.

The flattened and frequently umbilicated pustules of this form of the disease, are almost always mingled with conoidal and globular pustules. They also occasionally assume very various shapes when several of them happen to be congregated in the same spot and fused together.

445. The course of the eruption is occasionally *irregular*, so that papular elevations, pustules, and incrustations are found at the same time in the same individual. This circumstance is remarkable when the pustules appear in successive crops; very frequently, however, the course of the umbilicated pustular varicella, during the first week, is as regular as that of small-pox itself.

When the eruption of this species of varicella is confluent, the face may become entirely covered with thin yellowish and lamellar incrustations similar to those of small-pox; but in the variety of varicella we are now discussing we observe no secondary fever, and this character distinguishes it certainly from legitimate small-pox.

The umbilicated pustular varicella runs its course in from twelve to fourteen days; it almost always ends happily; patients on their recovery carry about with them, for a long time, traces of their disease, and are sometimes marked with true cicatrices similar to those of small-pox. (a)

(a) The uniform absence of secondary fever in varioloid, as assumed by the author, is not entirely accurate. The fever occurs but seldom; still it does occur. On the subject of the appearance and general course of varioloid and of its sameness with the variola, Dr. Mitchell's

experience and my own were recorded in the paper before cited. As the narrative and argument are not long, the reader may not perhaps be displeased at their introduction here.

"That in an epidemic season, in which the tendency to cutaneous disease was very great, as in the years 1823 and 1824, the poison of small-pox should affect the then three privileged classes, viz., those who had had the disease naturally in early life, those who had had it by inoculation, and those who had been vaccinated, was not an anomaly.

"The operation of the variolous poison, when it took effect on the vaccinated, was often similar for the first few days to that on the unprotected, that is, on those who had never been subjected to inoculation or vaccination, or who had not been in any former period attacked with the small-pox. The fever, the gastric distress, and pains in the back and head, were occasionally as distinctly defined, as in the first period of the unmitigated disease. In some cases, the activity of the circulation, and the determination to the brain, seemed to be greater in the modified, than in the unprotected subject. The eruption on such occasions, was at first of maculæ, in abundant crops, of a crimson colour, with scarlet borders, especially copious about the back, shoulders and hips. But it is worthy of observation, that these maculæ, smooth and without elevation, would for the most part disappear, without leaving corresponding papulæ. Where the eruption was constant, and proceeded on to maturation, the pustules were usually fewer, the constitutional disturbance at the time less, and the subsequent process of desiccation, more rapid than in the genuine small-pox. Nor was there in general, secondary fever in the former, as in the latter. In these particulars, there were, however, some notable varieties; so that some who had been previously vaccinated, were attacked with such violence by the varioloid disease, or modified small-pox, as to have their lives endangered, and the face subsequently marked with the scars in the pustules. But, in general, the disease in this form was milder, more obedient to remedies, and very rarely of fatal termination.

"It will be observed that we speak of the disease occurring in the vaccinated, and possessing the characters already described as necessarily the product of variolous poison, or that same contagion, which, in the unprotected, produced the natural small-pox. The identity of cause of the two forms of eruptive fever, variolous and varioloid, has been, we know, denied by some; but, for ourselves, we see no ground to doubt the sameness, if we are to be swayed by the customary laws of evidence. We are led to this conclusion by the following reasons.

"1. Some of the vaccinated have at all times, since the introduction of the cow-pox, had, on exposure to the poison of the small-pox, an eruptive fever similar, in appearance and symptoms, to the latter disease, except on the score of its mildness.

"2. Some of the vaccinated have, on the introduction of small-pox matter by inoculation, had a pustule with an extensive areola, accompanied by fever, and a partial eruption on the other parts of the body.

"3. In the same family, persons previously vaccinated have had this modified eruptive fever, while living with, or nursing, those labouring under the natural small-pox; and *e converso* persons have had the natural disease without having been exposed to any other known cause than living with others who were then suffering under, or had just recovered from, the modified or varioloid disease.

"The fact that small-pox, by effluvia, or in the casual way, can take place within a limited time after the cow-pock, was first observed in Mr. Malin's case, see *Med. and Chir. Review*, No. 58; and I think Mr. Bevan's case (*Med. and Phys. Journal*, p. 455, vol. v.) is an instance of the same kind." 'Hence,' continues this writer, 'it appears there are two different sets of eruptive instances, to wit, 1. Those of the casual small-pox cotemporary with the vaccina. 2. Those of the casual small-pox supervening a few days after the constitutional affection in the vaccina.' Dr. Pearson was one of the earliest and most zealous advocates for the practice of vaccination, and his opinion, as just given, comes in most opportunely in the

<sup>1</sup> An examination of the report of the committee of the House of Commons, on the claims of remuneration for the vaccine-pock inoculation, containing a statement of the principal historical facts of the vaccina. By George Pearson, M. D., F. R. S.

446. *Structure of the pustules.*—The flattened pustules of the umbilicated pustular varicella are extremely analogous, in point of structure, to those of small-pox. As in these the duller white colour and depressed centre of the pustules are owing to the presence of a small pseudo-membranous disc deposited between the corion and epidermis, and adherent to the latter. Perhaps the sole anatomical difference between the two eruptions lies in the minor degree of development of this false membrane, and of the papular eminence upon which it is situated, in the modified small-pox. These eminences, which in legitimate small-pox almost invariably sink down and become ulcerated, are very seldom so affected in the pustular varicella, true suppuration occurring but very rarely indeed in the interior of the pustules of modified small-pox.

447. *Causes.*—Umbilicated pustular varicella prevails at the same times as small-pox and the other varieties of varicella, and is engendered under the same influences; it appears more especially in the beginning as also at the end of variolous epidemics, attacking particularly those subjects who have had small-pox or been vaccinated.

During the epidemic small-pox of Marseilles, in 1828, of 30,000 persons vaccinated, nearly 2000 were attacked with spurious, and some few with apparently true variola; of this number, twenty fell victims to the disease; of nearly 2000 individuals who had had natural small-pox, about twenty were affected with the prevailing epidemic, of which number four died. Of 8000 not vaccinated, nearly 4000 were attacked with small-pox and of these 1000 perished.

Pustular varicella has been said to have been observed especially among the vaccinated who have had few pustules, or among those in whom the vaccine pustules had been pale and without activity, or, further, among those in whom the pustules had been opened before their perfect evolution; these statements all require confirmation.

During the Marseilles epidemic it was thought that the pustular varicella could be traced as attacking in preference those individuals whose vaccination had been performed at the remotest periods, and I have been assured that this form of the disease was actually most severe in those who had been longest vaccinated, two statements the accuracy of which M. Gendrin has disputed, so that the question is still undetermined.

The contagious principle of small-pox, operating upon individuals little susceptible of its influence, and who have neither had small-pox nor cow-pox, may engender the umbilicated pustular varicella.

The same individual may be several times affected with this species of eruption by renewed exposure at different times to the variolous contagion.

Pustular varicella has been seen in individuals who have never had small-pox, and who have been vaccinated fruitlessly.

The inoculation of the fluid of the umbilicated varicellar pustule is not commonly followed by any symptom of general infection, and only produces a local eruption analogous to that of cow-pox. (Dugat.) The inoculation, however, may be succeeded by a general eruption with or without initiatory, certainly without secondary, fever. Lastly, the inoculation of this matter performed upon individuals who have never had such an eruption, and who have never been vaccinated nor been affected with small-pox, may cause the development of legitimate variola of various degrees of severity, as has been demonstrated by the experiments of Messrs. Dugat and Lafont-Gouzi, in opposition to the opinion of M. Gendrin, who had maintained that varioloid was transmitted by inoculation without ever approaching variola in its characters. Further, small-pox has been seen rising from the contagion of pustular varicella, and pustular varicella springing from the contagion of small-pox. In the Marseilles epidemic

present argument. In his time, we see that the liability of small-pox coming on after vaccination, was thought to depend on the recency of this latter operation, merely, we presume, by a process of negative reasoning, for there were no opportunities to ascertain the liability of those vaccinated for a length of time, as the practice was then but of few years' adoption. In our day, we have seen an opposite opinion held, viz., the greater susceptibility to small-pox in those vaccinated for a term of years. Experience has shown long ago the fallacy of the first belief; the second must, we think, be abandoned on the same showing."

mic a young man who had neglected vaccination was attacked with small-pox and died; his cousin, bearing handsome points of cow-pox pustules upon his person, went to visit this young man, and caught a pustular varicella; at the same time a brother, who had not been vaccinated, was infected with the most characteristic small-pox imaginable by others of the family who had been vaccinated and were now labouring under pustular varicella.

448. *Diagnosis.*—During the first week the resemblance between variola and umbilicated pustular varicella is such, that there is no means of distinguishing between them.

The pustular varicella differs from confluent small-pox in the more rapid progress of its pustules when they have attained their height, and in the non-occurrence of secondary fever; the areolæ are also inflamed in a less degree, and the pustules are more rarely followed by cicatrices.

This species of varicella differs from distinct small-pox, not, as has been stated, in the extreme irregularity and rapidity of its course, which is often as regular as that of small-pox, but by the entire absence of secondary fever.

449. According to Dr. Lüdgers, of Copenhagen, the pustular varicella (varioid) differs from small-pox in the irregularity of its course, the uncertainty of its symptoms, the mode in which its pustules appear, which is in successive masses, occupying first the extremities, then the trunk, and lastly, the face; in the imperfection of the suppurative stage, the promptitude with which the desiccation is completed, and the failure of the secondary fever. In my opinion, it is to this last circumstance that we are especially to cling; for, in the majority of cases, pustular varicella advances with the greatest regularity, and variola itself is not without a considerable number of individual anomalies.

Others imagine that pustular varicella differs from variola in this, that the inflammation extends to the substance of the corion in variola, whilst in the varicella, it stops at the surface of the papillary body, which is the reason of its seldom leaving cicatrices after the fall of the scabs.

It has also been said that the pustules of *modified* small-pox consisted of no more than a single cavity; but this peculiarly belongs to the varicellæ with globular and conoidal pustules alone.

M. Gendrin maintained that umbilicated pustular varicella (varioid) differed from small-pox in the structure of the pustules, which, in the varioid, contained no fluid, did not appear multilocular, and always ended in resolution. M. Guersent has, with justice, disputed the accuracy of this proposition; after a careful examination of the pustules of variola, and of varioid, during the course of the first week, he was frequently unable to perceive any difference between the one and the other. My own researches agree with those of M. Guersent, § 440; and M. Gendrin's statements respecting the structure of the varioid pustule, are, in truth, only applicable to a very rare variety of varicella, namely, the papular.

*Ptyalism* is a symptom in small-pox which only happens among adults, and cannot be assumed as a feature distinguishing true small-pox from pustular varicella.

The *odour* of small-pox has been said to be different from that of pustular varicella; if such be the fact, it requires such delicacy of organ to appreciate the circumstance, that it can never be made available in practice.

450. Messrs. Favart and Robert, of Marseilles,<sup>1</sup> perceived full well that umbilicated pustular varicella (varioid), followed the same course as the confluent small-pox, during the periods of incubation and eruption, and that the two diseases first assumed different characters after these periods: small-pox continues to pursue its course; to the swelling of the face succeeds that of the hands; the pustules go on increasing, and acquire a whitish colour; the inflammation of the face and hands is then at its height; the spaces between the pustules become of a bright red; the fever, which has been almost insensible since the appearance of the eruption, is lighted up afresh, constituting the secondary or suppurative fever; the pustules of the face, followed immediately afterwards by those of the hands and other parts of the body, pass from white to yellow; lastly, the tume-

<sup>1</sup> Robert. *Précis historique de l'épidémie qui a régné à Marseille, et vues nouvelles sur la vaccine.* Marseille, 1828.

faction of the face subsides, the eyelids become of their natural size, and the patient regains the use of his sight (this happens on the tenth or eleventh day); from this period the pustules grow brown, shrink, become hard and dry, and the friable crust is detached from the twentieth to the twenty-fifth or thirtieth day from the invasion, leaving exposed the deep cicatrices that ever afterwards proclaim the attack of the disease, at first of a deep red colour, and only in the progress of time acquiring something of the tone of the skin. In the umbilicated pustular varicella (varioid), on the contrary, the suppurating stage is stationary, and there is no secondary fever; arrived at the eighth, ninth, or tenth day, the disease stops of itself, the pustules dry up, and the crusts fall off from the skin towards the twelfth, thirteenth, or fourteenth day.

To resume, if there be pretty evident differences between confluent variola and the umbilicated pustular varicella, this disease is assimilated in numerous particulars, with distinct variola, from which, however, it still differs, by the constantly progressive state of its pustules during what should be the stationary and suppurating periods, and the absence of the secondary fever.

The flattened and frequently umbilicated form of the pustules sufficiently distinguishes this from the other varieties of pustular varicella.

451. *Prognosis*.—The eruption of the umbilicated pustular varicella is usually distinct; and, as has already repeatedly been said, is unaccompanied by secondary fever. Neither does it present the formidable symptoms of *nervous* variola, of *laryngeal* variola, nor of *hemorrhagic* variola. It is therefore usually a disease of little severity. During the epidemic of Marseilles, nevertheless, twenty persons who had been vaccinated died, and in several others the attack possessed a character of great severity.

This modified small-pox may even occasionally present more formidable symptoms than legitimate distinct variola.

Pustular umbilicated varicella (varioid) preserves occasionally at least, if it does not uniformly give security from small-pox. In an epidemic small-pox which appeared at St. Paul-de-Leon, in 1826, M. Guillon having inoculated six hundred and sixty children with the matter from the pustules of a vaccinated subject labouring under the prevailing disease, the greater number had nothing more than a local eruption analogous to that of cow-pox or inoculated variola, and not one of them contracted small-pox. Messrs. Gendrin and Cullerier have also seen varioid taking the place of variola; M. Bourgeois saw two children, who, after having had the varioid, tended with impunity two brothers attacked with variola; lastly, M. Cullerier inoculated children who had never had more than the *varioid* with the matter of *small-pox*, without the operation being followed by any eruption. However this may be, my own opinion is that the umbilicated pustular varicella does not give immunity against small-pox to the same degree as cow-pox and legitimate variola.

The time which has elapsed between the vaccination, or a previous attack of variola, and the evolution of umbilicated pustular varicella, does not appear to cause any modification in the progress and severity of this eruption. Thus, this species of varicella has been seen of considerable severity in individuals vaccinated but a few weeks previously, and, on the contrary, with a character of extreme mildness in persons who had been vaccinated, or who had had the small-pox twenty years before. (a)

452. The *treatment* of umbilicated pustular varicella is the same as that of distinct small-pox.

453. Although individuals have been subjected to the influence of natural or inoculated small-pox, or to that of cow-pox, it has been proposed to re-vaccinate them from time to time, with a view to render them unsusceptible of the attacks of the pustular varicella (*vide* Vaccinia).

#### Historical Notices and Particular Cases.

454. The umbilicated pustular varicella is probably as old a disease as small-pox itself, for it is indisputable that eruptions of a

(a) This assertion, of the entire accuracy of which I have had abundant evidence, merits serious attention; and is a sufficient reply to those who would persuade us that vaccinia wears itself out after a certain period.

similar nature were observed among those who had had the small-pox naturally, or by inoculation,<sup>1</sup> long before the development of this modification of variola was made the subject of particular study in the vaccinated, among whom it occurs most frequently. A very considerable number of the vaccinated have been attacked in each of the small-pox epidemics that have recently prevailed; and the vaccinators have spoken of it as a *spurious small-pox*, due to a faultily performed or imperfectly developed cow-pox inoculation, or as a variety of *varicella* produced by a peculiar and specific contagion. The opponents of vaccination again, and those who believed that cow-pox did not always afford security against variola, have triumphantly pointed to this eruption as a legitimate small-pox, and assumed its occurrence as proof positive of the inefficacy of vaccinia as a preservative from this formidable disease.<sup>2</sup> Lastly, Dr. Eichhorn has published a new division of the variolous eruptions observed among the vaccinated.<sup>3</sup>

455. Some writers, having given the title of *varioid* to all the varioliform eruptions observed among individuals who have been vaccinated, have described these eruptions with such generic characters as are rather to be met with in the conoidal and pustular varieties of varicella, than in the umbilicated pustular form of the disease. Thus it has been said, that elevation, and basilar induration of the pustules were scarcely to be detected; that their areola was irregular and badly defined; that after the fourth day the apices of the spots were of a pale watery white; on the fifth, that they became serous and rounded; on the sixth, that the fever and areola disappeared; that the serum occasionally became opaque or red without assuming the purulent character; that it escaped from the greater number of the pustules, and was absorbed from the remainder; lastly, that the seventh day was marked by the desiccation of the pustules and the convalescence of the patient.

<sup>1</sup> Thomson. Hist. sketch of small-pox, 8vo. Lond., 1822.

<sup>2</sup> Pougens. Petite-vérole chez plus de deux cents individus vaccinés, observée à Milhau, en 1817, 8vo. Milhau, 1817.—Gastellier. Exposé fidèle de petites-véroles survenues après la vaccination, 8vo. Paris, 1819.

<sup>3</sup> Dr. Eichhorn divides the variolous eruptions observed among the vaccinated into: 1. *True variola*.—2. *Purulent varioid*, differing from the former only in the speedy desiccation of the pustules, and the absence of secondary fever, although the oedematous swelling of the skin proper to the legitimate small-pox occurs here also, during the suppurative stage.—3. *Lymphatic varioid*, the eruption being full of transparent fluid. 4. *Verrucous or warty varioid*, the spots remaining solid to the end and never becoming filled with fluid. 5. *Papular varioid*; a disease which occasionally appears to be attended with danger, and not merely a *modified* but a *true* small-pox under a papular form. 6. *Varioid fever*.

Dr. Eichhorn attaches the greatest importance to the umbilicated depression; if but one spot of an eruption present this character, he holds it warrant enough of the varioid nature of the disease. This author also designates as *pustular* a spot, that is *umbilicated*, whether it contain *pus* or *lymph*; he reserves the title of *vesicles* to spots filled with *lymph* and *not umbilicated*: the *varioid spot*, whether filled with *pus* or *lymph*, or *solid*, is depressed in the centre, or umbilicated; the *varicellar spot* may be *purulent*, may be a *true pustule*, but it is not umbilicated.

Eichhorn maintains that *varicellæ* only excite *varicellæ*, and never variola or varioid, and concludes that varicella is the effect of a peculiar contagion. He distinguishes this disease into: 1. *Vesicular, bullous or globular*, and, 2. *Cellular or pustular* varicella. The former has occasionally been mistaken for pemphigus; the latter is not completely emptied by a puncture. The pustular varicella presents a considerable number of varieties:

(a) *Lenticular or lymphatic* varicella, the eruption of which appears either flattened or pointed, and is afterwards filled with purulent serum. (b) *Verrucous* varicella (horn-pock, stone-pock) shaped like the former, but solid and warty; its point is also distended with a lymphatic or purulent fluid. (c) *Conoidal or acuminate* varicella; the eruption of which is pointed. (d) *Spongy* varicella which seems to be intermediate between a and b; the eruption in either of them swelling and becoming *spongy*. The whole of these forms arise from one cause,—the *varicellar contagion*.

The diagnosis of varioid from varicella, according to the same author, is as follows: 1. During the period of eruption, variola and varioid present stigmata of a dusky red, ill defined, without hard nuclei, and are succeeded by soft pustules or vesicles, most commonly after an interval of no more than six hours, in consequence of which papulæ are not usually observed. 2. At the height of the disease, the pustules of varioid are umbilicated. Several among those of varioid have the depressed centre also. The pustules, vesicles, or whatever they be, of varicella never show this characteristic feature. 3. During the period of desiccation, variola and varioid are followed by scabs in the form of sections of a cone; varicella never leaves crusts of this shape. 4. The cicatrices left by variola and varioid are ragged or uneven. Varicellæ only give rise to cicatrices, when they have been excoriated, or a purulent fluid has been long confined within their interiors. These cicatrices also when they do occur, are smooth on the edges and even, and not always of a round, but frequently of an oval form.

Although I do not agree with Dr. Eichhorn in all his opinions, I have thought it fair to give a statement of them from the great pains he has been at to develop them fully. (*Vide* Eichhorn. Neue Entdeckungen über die Verhütung der Menschenblattern bei Vaccinirten, 8vo. Leips., 1829.)

Eichhorn considers the varioloid disease as a modification of small-pox, from which it differs in being unaccompanied by secondary fever. He thinks, too, that the varicellar eruptions are produced under the influence of a specific contagion, distinct from that of small-pox and varioloid.

In these latter times many observations and inquiries have been made into the characters<sup>1</sup>, and the inoculation<sup>2</sup> of the pustular variellæ (the varioloid of many modern authors). Some remarks of a comparative nature have also been published on the modified pustular diseases of sheep denominated Clavelée in France,<sup>3</sup> which is transmissible by inoculation.

CASE LXVI.—*Umbilicated pustular varicella occurring during the epidemic prevalence of small-pox in an individual previously vaccinated.* M. Fl., twenty-three years of age, began to complain on the 18th of September, 1825, of a feeling of fatigue, uneasiness, and disrelish for food: an epidemic small-pox prevailed at this time in Paris. M. Fl. had been vaccinated in his youth, and his arm bore marks of the cicatrices left by regular cow-pox. The state of uneasiness described continued through the 19th; on the 20th, he felt greatly depressed, yet went abroad; on returning home in the evening he had a violent shivering fit, accompanied with distracting headache. He passed the night without sleep, feverish and restless. On the 21st, epigastric heat and pain; nausea; tongue foul, and red at the point; headache; shivering fit, to find relief from which, M. Fl. took a hot bath at a high temperature, but the symptoms did not continue with the less violence. On coming out of the bath he went to bed; he was sick, and repeatedly vomited a quantity of bilious stuff during the day, and course of the succeeding night; the head was excessively hot, the legs extremely cold. On the 22d, I was summoned. I found the patient vomiting, and he informed me that the slightest movement was enough to induce the act, which was accompanied by violent convulsive motions of the stomach, and painful eructations (*twenty-five leeches to the epigastric region; mucilaginous drink*). The leeches continued attached for two hours; after their fall the bites were covered with an emollient cataplasm. In the evening the patient was delirious, and this state continued far into the night (*weakened mustard cataplasms to the insteps; drink as before*). At midnight, (fourth or fifth day of the disease,) an eruption was discovered, especially upon the breast, very much resembling flea bites in its appearance. 23d.—Several small distinct red pustules were scattered over the trunk and extremities; a few were also situated on the face; the patient had perspired profusely; the headache and vomiting had diminished. 24th.—Second day of the eruption, which is now very abundant on the face; the headache had ceased; the vomiting returned again at night; the perspiration was incessant and copious (*barley water for drink*). The night was pretty tranquil. 25th.—Third day of the eruption, which is making marked progress; the pustules are also becoming more numerous. The sweating has now ceased: the patient complains of a tense, stiff, and burning sensation in his face, as if it was covered with a mask of fire. In the afternoon, the patient rambled in his talk for about a quarter of an hour; in the evening he was quieter (*barley water with one-fourth part of milk*). 26th.—Fourth day of the eruption; no sleep last night; the pain of the face very distressing; restlessness; the patient rambles from time to time, and complains repeatedly of heaviness of his head. The foot bath three times a day relieved this symptom. The urine, which was high-coloured for the first few days, has been transparent and yellow during the last three. The pustules of the thighs are now well evolved. 27th.—Fifth day

of the eruption; the conjunctivæ are injected; every part of the surface of the body from the crown of the head to the soles of the feet, as well as the lining of the mouth, and the mucous membrane of the glans is covered with pustules. These are in greatest numbers on the breast, thighs and face; eight were counted on the forehead, and one hundred and nineteen on one of the cheeks.

Some, indeed the greater number, of the pustules are voluminous, regularly circular, flattened, depressed in the centre and without areola, or surrounded at most by a very pale pink circle. The matter of the pustules is neither watery nor sero-purulent. They are firm and rather unyielding to the touch; and are evidently distended by a concrete substance which does not flow out when the cuticle which covers them is punctured or is removed. Several pustules are observed of a larger size, of an irregular shape, and evidently formed by the fusion of two or three of the ordinary pustules into one. Others of a smaller size and globular are about a line in diameter filled with an opaque and whitish fluid, and surrounded by a red and pretty regularly circular areola, interrupted, however, in those situations where the pustules are confluent, or where pustules of a larger size are approached. The part of the skin upon which pustules of the latter description are developed is erythematous. Lastly, not more than from fifteen to twenty small conical pustules can be counted over the whole surface of the body; the generality are flattened and umbilicated. The patient has no cough, and no affection of the bowels; the pulse is natural; the tongue is covered with a thick white fur, and there is little thirst (*pediluvium; barley-water*). The heat of the face was now greatly lessened; all the stormy symptoms had subsided and the patient slept. 28th.—Sixth day of the eruption. The whole of the pustules of the face were in full suppuration; three or four on the nose and several on the cheek presented a black, dry, central point. Several, on different parts of the body, seemed to have stopped short and were no larger than those of impetigo. The pustules of the face were not so flat, and were whiter and more purulent than those of the hands; the rest were pink-coloured; the tongue was getting gradually cleaner. 29th.—Seventh day of the eruption. Tranquil and uninterrupted sleep through the preceding night. The progress of the pustules presents some variety: those of the hands that are flattened and umbilicated have not yet changed either their form or their colour. Several of the same description situated on the forearm are purulent and have a yellowish-white tint; others on the nose and trunk are yellow and almost dry, with a crust in their centre (*barley water with milk; chicken-broth*). 30th.—Eighth day of the eruption. An excellent night; the detachment of the crusts going on; from the face, the greater number have already fallen, leaving small red marks behind them, each of which presents a central, more highly-coloured and depressed point. None of these spots has the livid colour of those that follow legitimate small-pox. The pustules on different parts of the body are shrinking apace; the tongue is moist and white in the middle. (*Broth, semolina*.)

31st.—Ninth day of the eruption, thirteenth of the disease. The night has not been so quiet; quantities of small lamellar scabs are found in the bed, having the form and dimensions of lentils. The pustules dry up without rupture of the epidermis; the appetite has returned, and the convalescence is complete.

A few small cicatrices were left on the face bearing a striking resemblance to those of small-pox. Two months after the invasion the marks of the disease had not entirely disappeared.

Few cases of varicella occur with so many points of resemblance to small-pox as the one just detailed. The eruption, in fact, took place on the fourth day from the attack, after severe precursory symptoms, such as delirium and repeated attacks of vomiting, and during the prevalence of an epidemic variola. The eruption consisted of numerous flattened and umbilicated pustules, and the face was puffed and inflamed; but the eruption differed from that of small-pox in the rapidity of its progress, which was such that the whole of the pustules were dry by the thirteenth day of the disease, and in the complete absence of pyralism and non-occurrence of secondary fever.

## 2. CONOIDAL PUSTULAR VARICELLA.

Vocab. *Varicella coniformis* (Willan); *Varicella* (Plenck); *Swine-pox*.

456. In this variety the eruption is preceded by febrile symptoms, occasionally of great severity, which last for two or three days. Frequently also at the end of twenty-four hours a crop of small red spots, similar to flea-bites, appears upon different regions of the body, and change for the most part into *pointed* elevations like those of small-pox in their first stage. The day after their appearance these risings preserve their original form, and exhibit an *opaque white speck* on their summits; they are never completely transparent like the vesicles of *chicken-pox*. Their bases are not so hard, nor so much inflamed as those of the pustules of small-pox, but more so than those of the vesicles of chicken-pox. The fever usually ceases after the eruption appears. On the third day the bases of the spots are more inflamed; on the fourth and fifth days they continue nearly in the same state; on the sixth they begin to shrivel and to dry upon their summits. On the seventh those of the face are transformed into prominent crusts of a yellow or yellowish-brown colour. On the eighth and ninth these crusts are detached, many of them leaving small cicatrices. On the following days the scabs fall from the other parts of the body.

The pustules of this variety of varicella may be developed successively so as to protract the eruption to the twelfth or thirteenth day.

The pustular conoidal varicella is observed during the epidemic prevalence of small-pox, most commonly attacking those who have been vaccinated, and occasionally those who have already had small-pox. This form is always well marked on the face; a number of umbilicated pustules, however, are often observed on the thighs.

M. Fontaneilles has shown that this form of varicella could be transmitted by inoculation.<sup>1</sup>

*Historical Notices and particular Cases.*

457. The pustular *conoidal* varicella was described by Willan, who classed it among the *vesicular* diseases. It is indisputable, however, that an *opaque white point* is almost uniformly developed on the apices of the eruption, in consequence of the formation of a false membrane, and that the greater number of the spots become purulent before their termination. I have collected several cases of this variety myself; the one which follows I have borrowed from Messieurs Bérard and Delavit.

CASE LXVII.—*Conoidal pustular varicella*.<sup>2</sup> Louis, aged fifteen, and having been vaccinated, was seized in the evening with alternate chills and flushes, supra-orbital headache, lassitude, and pain of the limbs. Second day, the same symptoms continued; an eruption of a number of spots (*boutons*) appeared on the hands; these were at first of a red colour, but became white within a few hours. Their centre, uniformly raised, ended in a point. They are but little elevated above the level of the skin, and surrounded by a broadish pale red circle; they disappear on pressure, which is not painful. Second day of the eruption: additional spots developed on the face, exactly similar to those that have been already described. Third day: headache over the eyes, intolerance of light, tongue yellow, with red spots on its edges, mouth clammy, pain of epigastrium increased on pressure; the pustules of the hands are dry, and present in their centres a pale, gray and slightly adherent scab; they are surrounded by an areola of greater breadth than on the preceding days; those of the face are small and white; some of them present a gray point in the centre, which is not depressed, and are surrounded by a rosy circle, which melts into the natural colour of the skin. New pustules have appeared on the arms; these are red and of small size; their colour disappears on pressure, and they are surrounded by a broad areola (*tartrate of antimony*). The medicine caused vomiting of yellow matters; the bowels were relaxed; the belly felt hard and painful; perspiration; pulse natural; heat of surface not raised. Fourth day: no sleep, slight perspiration, headache, tongue as it appears in the best state of health; the pustules of the face are larger,

more prominent and whiter; the areolæ still broader; the pustules of the arms are white and silvery in their centre; no pustules are observed on the breast or lower extremities. Fifth day: the pustules of the face are shrunk, dry, and covered with a gray scab, which is flat and slightly raised above the surface of the skin; several of those of the arms have also dried, and formed red scabs, raised above the surface, rounded, and with the appearance of the pustules (*boutons*) of verrucous small-pox. Sixth day: general and profuse perspiration during the night; disappearance of all the morbid symptoms; the patient feeling perfectly well; the crusts of the face began to be detached, leaving in their place a slight red mark level with the skin. Seventh: recovery.

## 3. GLOBOSE PUSTULAR VARICELLA.

Vocab. *Hives*, *Varicella*.

458. In this variety the precursory symptoms are commonly more severe than in chicken-pox, and now and then approach those of small-pox in their long continuance and intensity.

The eruption appears in the form of red spots, larger than those of the preceding variety, occasionally wearing the aspect of a large papula, or bite of a gnat, and which, in the course of twenty-four or forty-eight hours, change into globular elevations, whose bases are not precisely circular, and whose centres are of a dull milky white colour. On the third and fourth days the eruption is propagated to different regions of the body; on the fifth, and often even on the fourth day the pustules become rounded, and the areola which surrounds them grows brighter; the pustules have then attained their greatest size, which occasionally equals that of the crystalline lens; they are of a dull white colour on their centres, upon which a kind of little disc, iridescent in its circumference, is observed; but they are transparent in their parts nearest their base. When they are opened with a lancet, and the epidermis is removed through the whole extent in which it is loosened, the opacity and central *whiteness* are found to be produced by a small pseudo-membranous disc, which differs from that of true small-pox in not extending over the entire surface of the pustule. On the sixth day, the circumference of the pustules passes or overhangs their bases, which are inflamed; next day many of them are soft and flaccid to the touch; the day following they are shrunk and wrinkled in their circumference; the eighth and ninth days, the desiccation advances, and laminated brownish crusts are taking the places of the pustules; on the tenth and eleventh, these scabs are detached from the skin, upon which marks of a deep red colour, and occasionally even cicatrices remain.

A few pustules are very frequently to be found, presenting the characters of the preceding varicellar eruptions, scattered among those which characterize the variety now under consideration.

As there is always some degree of pruritus of the skin, children are apt to tear the pustules with their nails; and the crusts which succeed them, now and then continue adherent for a long time, and leave small cicatrices when they are at length detached.

The eruption taking place successively during two and three days, pustules in different stages of their progress may always be found at the same time in patients labouring under the disease.

It may be transmitted by contagion, although the inoculation of its virus often remains without ulterior consequences.

*Historical Notices and particular Cases.*

459. Willan describes this variety of varicella as *vesicular*; but the spots have a *purulent* appearance in their centre, from the second day, in consequence of containing, like those of small-pox, a pseudo-membranous disc attached to the inner surface of the epidermis. I here republish the case of President d'Héricourt as an instance of this variety exhibiting general symptoms of some severity; the evolution and appearances of the eruption have not been described with sufficient care.

CASE LXVIII.—*Globose pustular varicella*.<sup>3</sup>—M. d'Héricourt, on

<sup>1</sup> Epidémie de Milhau, pp. 47—51.

<sup>2</sup> Bérard et Delavit. Op. cit. p. 129.

<sup>3</sup> Darcet. Hist. de l'éruption du Président d'Héricourt. Journ. de méd., t. 49, p. 303. 1798.

the 24th November, passed a bad and restless night. 25th.—Second day of the disease, the head was heavy and confused; there was pain of the stomach, and particularly of the fronts of the thighs and under the knees; the body was bent; the use of the foot-bath was followed by a fainting fit. 26th.—Same state; the night had been worse; no sleep; burning heat with passing chills. 27th.—Third day of the disease; several stains or small spots (*boutons*) were discovered on the face and neck; soon afterwards the patient felt himself worse than he had yet been, and was compelled to return to his bed. 28th.—Fourth day of the disease (second of the eruption.) The patient was still very ill, complaining of headache, and very distressing pain in the stomach, loins, and thighs; the eruption was more conspicuous, and in the evening sore throat was added to the list of sufferings (*the foot bath*). The patient perspired freely, and the eruption continued to be evolved; at one time the face appeared very full. The night was no better. 29th.—Fifth day of the disease. M. d'Héricourt was now told that he had small-pox, his medical attendant informing him that he would have communicated the matter before, but feared that he might be deceived, and his patient distressed by supposing himself attacked anew with this disease after having had it by way of inoculation. This day was more tranquil, and the night that followed, better than the five which had preceded it. 30th.—The eruption seemed to be completed; yet the patient again suffered severely from fever, and lost a few drops of blood by the nose. The night was stormy till about two o'clock in the morning of the 1st December, when the patient fell asleep. This day (fifth of the eruption) M. d'Héricourt was much better. Suppuration was established in the face, where there were no more than from a dozen to fifteen pustules (*boutons*), and extended gradually to the other parts of the body where the eruption was much fuller, especially on the back, on the arms, thighs, ears and hairy scalp. *The pustules (boutons) rose and became well rounded; the matter with which they were filled was already opaque and white, and they were surrounded by a red circle or areola perfectly characterized.* 2d.—Sixth day of the eruption; suppuration of the face completed, and well advanced over the rest of the body. *Several pustules, and these the smallest, already begin to dry off at their summits.* The patient, who had hitherto been kept extremely low, was allowed to take food for which he felt very much inclined. On the 3d December, seventh day of the eruption, the desiccation was well advanced, and the patient felt able to rise in the afternoon. 4th.—The strength returned with the appetite, and the patient who had had no passage in the bowels for three days, obtained to-day a copious and healthy evacuation. 5th.—(ninth of the eruption). The pustules of the face were completely dry,—it was forgotten to be stated sooner, that no salivation has occurred. From this time the pustules dried up, the scabs fell off, and the patient made a rapid recovery. A single pustule only left a mark on the face which will probably never wear out, and which is easily distinguishable from those that remain after the inoculated small-pox. The red marks of the pustules continued longer visible on the body than on the face.

#### 4. PAPULAR VARICELLA.

Vocab. *Ilorn-Pox.*

460. This variety does not differ from the others save in the circumstance that the greater number of the spots seem to miscarry, or to stop short at their first stage. In fact, after the precursory symptoms of a varicellar eruption, a crop of smaller or larger red-coloured papulæ is discovered upon the skin, which dry up or shrink away without being followed by crusts, never seeming to contain either pustular or pseudo-membranous matter in their interior. These papulæ are very generally mixed with a few of the lenticular vesicles of chicken-pox, or of the conical pustules which distinguish another variety of varicella; a circumstance which, added to the character of the prevailing epidemic, contributes to enlighten us in regard to the diagnosis. It is also common enough to meet with these varicellar papulæ scattered among the vesicular or pustular spots of the other varieties.

*Papular varicella* has been produced by inoculating with small-pox virus, individuals who had been previously inoculated or attacked with variola.

#### Historical Notices and particular Cases.

461. Cases and observations on this disease have been published by Black.<sup>1</sup> Peter Frank mentions this variety in his *Epitome*, under the title of *varicella solidescens*. It must be a very rare disease; I have never met with it myself, though I have repeatedly seen papular elevations scattered among the pustules of the conical varicella, and the vesicles of chicken-pox. Sims<sup>2</sup> has given an account of an epidemic *modified* small-pox, under the objectionable title of *chicken-pox*, in which *papular* and *globular varicellæ* were observed.

#### 5. VESICULAR VARICELLA. CHICKEN-POX.

Vocab. *Chicken-pox, Varicella Lymphatica.*

462. *Symptoms.*—The attack of vesicular varicella is preceded by slight febrile symptoms, which continue for twelve, or at longest forty-eight hours. The febrile state, indeed, is often so slight as to escape notice,—a little depression and headache do not prevent children from engaging in their usual play. Such extreme mildness in the precursory symptoms of chicken-pox is not, however, an invariable circumstance; in some rare cases the invasion of the disease is proclaimed by violent pains of the epigastrium, nausea, vomiting, &c.<sup>3</sup>

The eruption of chicken-pox, although usually distinct, is occasionally confluent.<sup>4</sup> On the first day of its appearance it is characterized by small red superficial and oblong or nearly circular spots, of larger size, and more irregular in their outline when they are formed by two or more fused together. In the course of the next day a prominent vesicle filled with a perfectly transparent and colourless or pale citrine tinted fluid, which flows out readily when the cuticle is pricked, is developed in the centre of the greater number of these prominent spots. On the second day this vesicle is nearly a line and a half in diameter; it becomes *pointed*, or it increases a little more slowly over a larger surface, assuming a rounded form. New spots appear successively, in the centres of the majority of which, a vesicle soon arises, their bases being occasionally a good deal inflamed. On the third day the colour of the lymph becomes yellowish, and this is the only change the vesicles are found to have undergone. On the fourth day, such vesicles as have not been accidentally ruptured, shrink in size, and grow wrinkled in their circumference. On the fifth, a small scab, which is adherent to the skin, forms on the centres of the vesicles, and a small quantity of turbid lymph is included in their circumference, a change which occasionally gives them an umbilicated appearance. On the sixth, small yellowish or brown scabs replace the vesicles. On the seventh and eighth, the scabs fall off and expose red and undepressed marks upon the surface of the skin, which continue visible for a few days longer.

During the course of this eruption, many of the elevations seem to abort: some remain in the state of *simple stains*, or *papular elevations*, and gradually disappear; others are surmounted by a very small vesicle only, which either bursts or shrinks away in a very short space of time.

*Distinct* vesicular varicella is commonly accompanied by only a very slight derangement of the functions of digestion and circulation. When the eruption is *confluent*, the general symptoms are usually more severe.

When the eruption proves successive, and is preceded or followed by other affections, such as erysipelas and ophthalmia, which are usually ascribed to its influence, or when such affections happen to occur at the same time as the vesicular varicella, the disease may be protracted through a period of two or three weeks.

<sup>2</sup> Sims. *Obs. on epidem. diseases*, 8vo. Lond., 1773.

<sup>3</sup> Sims, *ut supra*, p. 115.

<sup>4</sup> Ring. A case of confluent chicken-pox. *Med. and Phys. Journ.*, v. 14, p. 141.

463. *Causes*.—Chicken-pox may be transmitted by the inoculation of the serous fluid of its vesicles, or of that of the pustules of the umbilicated, conical, and globular varieties of varicella, or by the air charged with the contagious miasm of either of these. "I remember on two different occasions," says Vieusseux, of Geneva, "to have seen a transient SMALL-POX, the pustules of which continued five or six days; they were full of opaque white pus, and were surrounded by such an inflamed circle as made me suspect them to be no true cases of small-pox, the more as I knew that one of the children affected had had this disease, and that the other infected his brother and sister with an eruption which was merely the common transient small-pox (*la petite vérole volante ordinaire*)."

Vesicular varicella or chicken-pox may produce legitimate small-pox, and true small-pox may engender chicken-pox. (§ 406.)

Chicken-pox is a disease which occurs almost exclusively among children; I have, however, seen it in adults and persons of riper years; Messrs. Hesse and Stieglitz were consequently mistaken when they stated that it only attacked the young. It is contagious, but in a less degree than small-pox and pustular varicella, and is transmissible by inoculation. This fact has been lately disputed very malapropos; for Willan and others succeeded long ago in propagating the disease in this way.

464. A certain number of cases of chicken-pox are almost invariably observed during the epidemic prevalence of small-pox, and of pustular varicella; or otherwise, chicken-pox very frequently follows these.

465. I have already said that chicken-pox appeared to me one of the varieties of the variolous eruption. Dr. Eichhorn,<sup>1</sup> however, assures us that he has observed vesicular variola prevailing epidemically when no cases of variola were encountered; and Mr. Barnes<sup>2</sup> has given a notice of an epidemic chicken-pox which prevailed at Carlisle in 1826, at a time when no case of small-pox had been seen for several months.

The epidemic occurrence of chicken-pox, independently of the other variolous eruptions, is extremely rare.<sup>3</sup> At Carlisle, small-pox had prevailed some months previously; and the chicken-pox was perhaps a last effort or effect of a variolous medical constitution. But in whatever manner this fact be interpreted, there is another much more satisfactorily demonstrated circumstance, namely, the almost constant occurrence of chicken-pox during the epidemic prevalence of small-pox. Other facts, moreover, prove that these two diseases are the effects of one and the same common contagion. (§ 406.)

466. *Diagnosis*.—When the vesicles of chicken-pox are fully developed, it cannot be mistaken for any other of the variolous eruptions, as it alone appears at the period of its height under the form of completely transparent vesicles.

The eruption in chicken-pox is general and scattered over the whole surface of the body, very differently therefore from the manner in which the vesicles of herpes phlyctenodes appear clustered together, and occupying a limited number of regions.

Acute pemphigus is characterized by bullæ, and not by vesicles; it is not contagious, and occurs independently of the prevalence of variolous medical constitutions.

When P. Frank described chicken-pox under the title of pemphigus varioloides, thus uniting two most dissimilar diseases in the same group, he evidently suffered himself to be led into error by a mistaken analogy.<sup>4</sup>

<sup>1</sup> Eichhorn. Handbuch über die Behandlung und Verhütung der contagiösfieberhaften exantheme, p. 437.

<sup>2</sup> Barnes (Thom.). Sketch of an epidemic varicella, which prevailed at Carlisle in the summer and autumn of 1826. (Edinb. Med. and Surg. Journ., vol. xxvii. p. 61.)

<sup>3</sup> I have looked through the indices of a great number of periodicals, such as the Journ. génér. de médecine, the Archives gén. de méd., the Journ. der Heilkunde of Hufeland, the Edinb. Med. and Surg. Journ., the Bibliothecæ of Ploucquet and the Repertorium of Reuss without meeting with any other instance of the occurrence of epidemic vesicular varicella, independently of prevalent variolous medical constitutions.

<sup>4</sup> It is even with more surprise that we find this author expressing himself as follows in another passage:

"Quas spurias dixere variolas, has, licet veras interdum præcedant ac annuntiare futuras videantur; licet ex insitione, cum pure varioloso ac optimo instituta, spurias provenisse referant variolas, ac licet ob similitudinem in multis cum variola legitima, tam communi, quam anomala sen abnormi, cum hac ipsa confundi facillime queant; ad aliud tamen morborum genus, utpote a variolis natura diversas, relegamus." De curand. hom. Morb. Epit., lib. iii. p. 97, 8vo. Vien., 1811.

467. The treatment of vesicular varicella is the same as that of distinct and benign small-pox.

Vesicular varicella does not give immunity from small-pox.

#### Historical Notices and particular Cases.

468. If at the present day there still prevails some obscurity in regard to various points in the history of vesicular varicella or chicken-pox, it is undoubtedly owing to several different kinds of eruption having been described under this title.<sup>5</sup> Besides the observations I have already mentioned, there are those of Willan,<sup>6</sup> who described three varieties of varicella according to the form of the vesicles, those of Heberden,<sup>7</sup> who was the first that imagined chicken-pox to be produced by a contagion different from that of small-pox, and those of Dr. Thomson,<sup>8</sup> who maintains, and in my opinion, has proved, that chicken-pox is a mere variety of variolous eruption, which all deserve to be particularly consulted.

CASE LXIX.—*Inoculated vesicular varicella* (Willan). M. P., aged seven years, was inoculated with the fluid of chicken-pox, October 23d, 1798, by two punctures in her right arm. October 24th.—A slight redness surrounded the punctures. 25th, 26th, and 27th.—The redness gradually increased, and was attended with a sensible hardness and elevation. 28th.—The appearances on the arm became much fainter. 30th.—Thinking the inoculation had failed, I did not inspect the arm again till the 3d of November, when she complained of an itching about one of the punctures. On examining the place, I found it red, elevated, and somewhat hard, with a small vesicle in its centre. November 4th.—The redness and hardness were much increased, and she complained of a sensation of tingling about the vesicle. Its size was equal to that of a variolous pustule on the seventh day after inoculation. In the evening, two small red eruptions appeared on her shoulder, and soon became vesicular. 5th.—The appearance on the arm continued the same, but no fresh vesicles were observed. 6th.—The redness on the arm was very faint; the hardness and elevations were abated. No further eruption appeared.

CASE LXX.—John Coles, aged ten months, took the chicken-pox by contagion, in July, 1799. On the third day of the eruption, he was inoculated from a pustule of the confluent small-pox. On the 9th and 10th he was feverish; pustule on the arm proceeding as usual. On the 11th, there were several small pustules round the place inoculated. On the 12th, an efflorescence appeared on the arm. On the 13th, there was an eruption of about 200 pustules. 18th.—The pustules had all suppurated. 20th.—Inoculated parts covered with a scab; pustules drying. Some of the vesicles of chicken-pox contained yellowish lymph, till the third day of variolous inoculation.

CASE LXXI.—Edmund Wilson, aged six months, was inoculated with chicken-pox, May 28th, by two punctures in the left arm. On the third day, May 30th, slight elevation and redness round the punctures. On the fifth day, more inflammation; in the middle of it, shining vesicles, flattish at the top, with an irregular margin. The child had been feverish the preceding night. He was inoculated this day with variolous matter, by two punctures on the right arm. Seventh day; the vesicles larger. Two other vesicles appeared on the left arm near the puncture. Ninth day, the primary vesicles broken; they appear bluish at the centre; there are many small vesicles around them. On the morning of the eighth day, the child was sick; through the succeeding night he was feverish and restless. Besides those round the punctures, there are twelve vesicles on different parts of the body, some of them rather indurated, others containing lymph. The pustules on the variolated arm are advancing. Tenth day: the child had a convulsive fit yesterday afternoon. He was feverish through the night, and had an efflorescence or rash over the whole body: vesicles broken and drying. Eleventh day, rash con-

<sup>8</sup> On the identity of chicken-pox and modified small-pox (Edinb. Med. Surg. Journ. v. xiv. pp. 518–657).

tinues; about fifty pustules appeared this morning. Vesicles on the left arm perfectly dry and scabbing. Pustules at the inoculated places on the right arm, much enlarged and surrounded by an efflorescence,—seventh day of variolous inoculation. On the fourteenth, the secondary variolous pustules are maturing, but they remain indented at the centre,—tenth day of variolous inoculation. Eighteenth day of the first inoculation,—fourteenth day of variolous inoculation—scabs over the places inoculated, the other pustules drying. Twenty-second day of variolous inoculation; pustules have been succeeded by scabs; some of them are separating.

#### 6. VARICELLAR FEVER (VARICELLÆ SINE VARICELLIS).

469. Certain fevers without eruption, arising from contagion of small-pox in individuals who have been vaccinated or inoculated, and from that of pustular or vesicular varicella, in subjects obnoxious to the influence of variolous contagion in all its shapes, have been described under the titles of *febris varicellosa*, and *febris varioloidosa*.

I have never myself seen a case of this kind of fever, for information on the nature and character of which, the works of Dr. Eichhorn particularly may be consulted.<sup>1</sup>

#### VACCINIA. COW-POX.

Vocab. Cow-pox, Grease, and Vaccine-pox.

470. On the teats of the cow, there occasionally occurs a particular kind of pustule, known in England under the name of cow-pox. The fluid of this pustule inoculated upon the skin of the human subject, gives rise to an eruption of similar pustules, to which the name of vaccine-pox, cow-pox, or vaccinia has been given. The disease thus communicated has the remarkable property of almost constantly preserving the constitution from the contagion of the small-pox, and always of notably diminishing the virulence of the variolous action, when it fails to give complete immunity from its influence.

471. The vaccine pustule appears three or four days after the inoculation of the virus; on the seventh and eighth days, it contains a viscid and transparent fluid, which is collected within a reticulated pseudo-membranous deposit. On the eighth, the pustule is surrounded by an elevated border, and an inflamed areola, and appears depressed in the centre. The contained fluid is at length changed into a brownish crust, which is detached towards the twenty-fifth day, leaving a puered and characteristic cicatrice on the skin.

472. *Inoculation of the vaccine pox.*—Vaccinia cannot in general be excited oftener than once in the same individual; it has, however, been communicated a second time.<sup>2</sup> It may also be produced in some rare cases in those who have had small-pox naturally, or by inoculation. In these individuals, however, a modified cow-pox or vaccinella is more commonly engendered. Cow-pox may be communicated to persons of all ages; but it seems to be more readily excited in children than in adults. Infants have been vaccinated a few hours after their birth; the operation, however, except under pressure of the epidemic prevalence of small-pox, may be deferred till the second or third month. It is seen, in fact, from the statistical tables of small-pox given by M. Mathieu, that this disease is infinitely rare from the period of birth to the age of six months. (a)

Certain seasons exercise an indubitable influence on the evolution of cow-pox; the heat of summer accelerates; intense cold retards its progress. Menstruation and pregnancy do not contra-indicate vaccination. (b)

(a) The proper time is about the third month after birth.

(b) Common ailments do not interpose an obstacle to vaccination,

<sup>1</sup> Eichhorn, op. cit. p. 407.

<sup>2</sup> Boffinet. Journ. compl. des sc. med., t. xxxi. p. 79.—M. Moreau, Professor of Midwifery, has given a case.—MM. Bricheteau and Boucher of Versailles, have seen several cases of these double vaccinia.—M. Trannoy assures us that he knew a lady who took cow-pox as often as she was vaccinated. On the other hand, M. Barry informs us, that he re-vaccinated above 300 individuals without producing a single pustule.

Healthy individuals do not require any preparation before being vaccinated. Occasionally, however, it is well, in the case of adults and the aged to diminish the rigidity of the skin by the use of the warm bath and the application of a soft poultice to the part selected for the punctures, the night before inserting the vaccine virus. In weakly children, of a lax fibre, the skin should previously be rubbed briskly with a coarse towel. By using these and similar means, individuals have at length been successfully vaccinated on whom the operation had been fruitlessly attempted several times before.

474. Certain circumstances, such as the existence of an acute inflammation of any of the viscera, too great a flow of blood from punctures carried too deeply, and peculiar medical constitutions, may prevent the success of the operation.

In a small number of subjects, some inscrutable condition or idiosyncrasy occasionally prevents the development of cow-pox. Vaccination performed on infants of three or four days old, fails on an average two in three times; it succeeds, on the contrary, ninety-eight times in a hundred, after six weeks.

475. *Methods of performing vaccination.*—The fluid of the pock of the cow's teat, or of the vaccine pustule of the human subject, may be inoculated by means of a *blister*, an *incision*, and a *puncture*.

1. *Blisters* have the twofold inconvenience of exciting an irritation, which tends much rather to prevent the action than to favour the absorption of the virus, and of causing an inflammation which, in young infants, occasionally terminates in ulceration.

2. *Incisions* are frequently followed by cutaneous inflammation, not vaccineal in its nature. This, however, is the only mode available, when all the virus at our disposal is contained in threads which have been soaked in the fluid. A superficial cut is made in the skin, a line and a half or two lines in length, in such a way as to cause little or no bleeding, into which a piece of the thread charged with the virus, a line in length, is introduced. The wound is covered with a bit of sticking plaster, and the whole secured by a turn or two of a roller. After an interval of two or three days, the dressing may be removed, and if the process of infection appears to have begun, the bit of thread may be drawn out of the wound.

The method by *puncture* is less painful, and also more certain in its results than that by incision. Two or three punctures are usually made in each arm with the point of a common lancet, or better, of a lancet constructed for the purpose, charged with the vaccine virus. Jenner was in the habit of making only one puncture in each arm; Dr. Eichhorn makes from sixteen to twenty altogether. If the vaccination be performed from arm to arm, which is the preferable plan, the lymph ought to be taken from the pustules on the fourth day of their evolution.

476. The *usual method* of performing this trifling operation is as follows: after having taken up on the point of a lancet or needle, a little of the fluid, the vaccinator, with the left hand, grasps the posterior part of the arm of the subject about to be vaccinated. He then makes the portion of skin that intervenes between his thumb and fore-finger tense, and with the right hand pushes the point of his instrument in a horizontal or slanting position a short way into the substance of the integuments. The thumb of the left hand being now applied over the puncture, he allows the instrument to remain for an instant, and when withdrawing it, presses gently upon the blade, as if to wipe it within the wound.

477. *Dr. Eichhorn's method.*—He advises from sixteen to twenty punctures to be made—a number which he esteems adequate in almost every case to secure individuals against the contagion of small-pox. Twenty-four or forty-eight hours after the appearance of the red circle, which is developed around the pustules, Dr. Eichhorn, with the matter of the nascent vaccine-pustule, vaccinates the same individual a second time; performing what he entitles the *proof vaccination*, in which he makes from four to six punctures. Three events may now occur. 1. The proof vaccination does not

if there be any urgency for having the operation performed. But in no case, unless small-pox be in the house, or the child be unavoidably threatened with its contagion, should vaccination be practiced on a subject whose skin is affected with any eruption or running sores.

take; the punctures do not rise; and the individual is then completely safe from small-pox. 2. The proof vaccination takes; but very small pustules only are developed, although possessing the form and structure of the true ones; the red circle is formed at the same time as that of the pustules already existing, and the whole dry off together; the individuals in whom this occurs are not secure. 3. The proof vaccination succeeds, and fresh pustules are evolved with so much regularity, and with the same slowness as the first; in the majority of these cases, the individuals are not protected.

These statements and experiments of Dr. Eichhorn deserve to be further inquired into and repeated.

478. If no other vaccine virus can be procured but that which is preserved between two plates of glass, or upon a piece of linen-rag, it must be softened or mixed with the smallest possible quantity of cold water, and then employed in the ordinary way by puncture.

To use the vaccine virus preserved in glass tubes,<sup>1</sup> the two extremities must be broken off, when by blowing gently into the tube, the matter it contains can be collected on a plate of glass and inserted by a puncture, as is done from arm to arm.

479. The vaccine pustule possesses its full energy on the fourth day of its appearance, and its contents present the following characters: 1. When several small punctures are made with the point of a lancet in the surface of a vaccine pustule, the contained fluid exudes slowly under the form of globules of a silvery colour. 2. When copiously shed over the surface of the areola this fluid resembles the slime left by a snail in its track. 3. It is viscid and mixed with difficulty with blood; it may be drawn out into threads between the thumb and finger; it sticks readily to the surface of a lancet or plate of glass applied to it; it dries quickly in the air, forming on the point of an instrument a gummy-looking crust. Threads imbibed with it become stiff when dry, and if they are then bent, it flies off in scales of a vitreous aspect and considerable hardness.

480. The whole of the fluid of a vaccine pustule does not appear to possess the same activity. Thus when a very large number of children are vaccinated from one or two pustules only, the first operated on have a better chance of infection than the last.

The vaccine virus possesses its full activity from the moment of its deposition within a pustule, and its power continues, although not in the same degree, till the eighth or ninth day of the vaccination. In general it is so much the more energetic as it is taken nearer to the period of its formation; the smaller the quantity of virus a properly developed pustule contains, also, the more energetic does it appear to be.

The virus of the vaccine pustules of young children is more certain in its effects than that taken from those of adults.

M. Bousquet assures us that the vaccine virus becomes rapidly deteriorated when preserved in tubes. It suffers less change when kept dry, between two plates of glass.

The scab of a vaccine pustule will occasionally transmit the disease; it is very uncertain however. (a)

Chemical analysis has showed the vaccine fluid to be composed of water and albumen; it has taught us nothing in regard to its peculiar contagion. (b)

481. *Symptoms.*—At the time each puncture is made, there is almost always formed around the point a superficial slight red circle

(a) In the United States, the scab or dried crust is almost the sole material used for propagating vaccine disease by vaccination. Although we might prefer, on the score of greater certainty of success, the fresh lymph, yet this cannot be procured in common, or more than once from one person, without injustice to the latter, owing to the irritation and inflammation which may follow and modify injuriously the progress of the vaccine pustule to entire maturation.

(b) M. Donné assures us that the microscope has not, as yet, revealed any distinctive character of vaccine vesicles or scabs.

<sup>1</sup> These tubes are six lines in length and capillary at their ends. To charge them with vaccine virus, nothing more is necessary than to touch the little globules of fluid, which flows from a puncture of the vaccine pustule, with the smaller extremity of the tubes. When sufficiently charged they are hermetically sealed in the flame of a candle. The virus thus collected is said to preserve its properties unimpaired for several years, if it is not exposed to too great a degree either of heat or cold. The tubes can be packed in the barrel of a quill, with a little bran, and sent anywhere.

from six to twelve lines in diameter, which disappears within a few minutes. This primary phenomenon is by no means a criterion of the future success of the operation as has been imagined; it follows punctures of every description. When the blush has disappeared, the puncture rises in the form of a small half lentil, looks slightly red, and continues longer than the first efflorescence; but it also subsides and vanishes in the course of a few minutes. Till the third and fourth days the vaccinated part presents no appearance of change (the period of incubation). At the end of the third day, or during the course of the fourth day, the evolution of the vaccine pustule commences: the finger readily detects a slight degree of hardness in the points where the punctures were made; upon these a small red elevation is not long of showing itself. On the fifth day this elevation becomes circular, and assumes an *umbilicated* appearance. The part is somewhat itchy. On the 6th day the red tint of each elevation becomes brighter, the circumference, which is surrounded by a red circle half a line in breadth, enlarges, and the centre of the pustule is more depressed. On the 7th day the size of the pustule increases; it spreads in its circumference and acquires a silvery aspect; the red colour which tinged it is lost in the central depression, and continues to occupy a very small part only of the outer margin. The red and very narrow circle, which up to this time has circumscribed the pustule, fades somewhat from the intensity of its colour; the inflammation extends to the subcutaneous cellular substance. On the ninth day the circumference of the pustule is still larger, its surface is more raised, and appears more turgid with the matter than ever; the red circle, the irradiations of which extended in streaks before, now acquires a more uniform rosy hue, and a perfect areola is formed. On the tenth day the turgid circumference of the pustule continues to spread, the areola acquires a diameter of from one to two lines, and the part of the skin upon which it is developed occasionally becomes indurated and very much swelled (the *vaccine tumour*). Its surface appears granular and slightly dotted, and by means of the magnifier a great number of minute vesicles filled with transparent fluid may be distinguished upon it. The person vaccinated experiences a biting heat and violent pruritus in the part affected, and a sense of weight and pain, which occasionally extends to the axillary glands, in the whole of the arm. This inflammatory period is often accompanied by some degree of fever and restlessness, with acceleration of pulse, &c., &c. On the eleventh day every thing continues in the same state as on the tenth. The vaccine pustule at this period is elevated from one to two lines above the level of the skin, and resembles a large lentil, the edges of which are raised in a pique. It is of a pearly hue, and its diameter varies from two to five lines; it feels hard to the touch, and resists pressure like a body intimately connected with the skin. During the whole of this period the vaccine fluid is contained within a reticulated pseudo-membrane, very nearly in the same manner as the vitreous humour of the eye is entangled in the cellular web. On the twelfth day the pustule begins to dry; the central depression assumes the appearance of a scab; the fluid, contained within the circular puffed circumference, limpid hitherto, now grows turbid and opalescent. The areola becomes pale, the general swelling subsides, and the cuticle covering it begins to scale. On the thirteenth day the desiccation advances in the centre; the pustule which has been cellular hitherto, now consists of but a single cavity. If it be punctured, its whole contents, consisting of a turbid yellow purulent matter, are evacuated. The areola changes into a circle of a pale purplish hue. On the fourteenth day the scab acquires the hardness of horn, and a tawny yellow colour something like that of barley-sugar. The circle which surrounds it decreases in breadth at the same pace as the vaccine tumour or general swelling subsides. From the fourteenth to the twenty-fifth day, the solid yellow crust becomes of a deeper colour, approaching mahogany in its appearance, and almost always preserves its umbilicated form. In proportion as the general swelling subsides, the scab seems to rise more and more above the level of the skin; it finally falls off between the twenty-fourth and twenty-seventh day, leaving exposed a deep cicatrix, studded with minute depressed points, similar to those which are often seen on the thin biscuits called wafers. (a)

(a) The vaccine pustule runs a given course of varus and of

482. Vaccinia is not always developed thus completely and thus regularly. 1. Occasionally but one or two pustules follow a much larger number of punctures. In the opinion of the majority of vaccinators, one pustule protects the constitution as effectually as six or a dozen (Messrs. Eichhorn and Robert, however, are of a different opinion). 2. The period of incubation may be prolonged to the twenty-second or twenty-fifth day, and even much longer,<sup>1</sup> or it may not extend to more than two or three days. 3. Irregular pustules occasionally arise from the accidental conjunction of two pustules evolved in the immediate vicinity of each other. 4. The vaccine virus occasionally produces in the same individual the true, and the modified cow-pox or *vaccinella*. 5. Vaccine pustules may appear on parts of the body where no inoculation was performed. It is almost always on inflamed surfaces which have lost their epidermis that these secondary pustules are developed, such as parts affected with chronic and impetiginous eczema, excoriated lichen, &c. These pustules, indeed, are occasionally produced by the accidental inoculation of the vaccine matter carried on the fingers in scratching from the original pustule to the abraded surfaces, when the constitution happens to have been but imperfectly modified by the first eruption. More commonly, however, the supernumerary pustules are the result of a secondary eruption analogous to that which even so uniformly occurs after the inoculation of the virus of small-pox. 6. In the negro and mulatto the inflammatory areola of the vaccine pustule is not very apparent, the skin, in its usual situation in the white, presenting in them merely a coppery appearance. In them, too, the cicatrix is red. Lastly, there occur *vaccinia sine vaccinis*. A well-constituted child, on the eighth day after vaccination complained of general uneasiness, and exhibited febrile symptoms which continued for a week. The eruption was looked for in vain. M. Pistono re-vaccinated the child, but without effect.<sup>2</sup> M. Petiet having vaccinated an individual who had had the operation fruitlessly performed the year before, this person, after an interval of eight days, was seized with fever which continued for thirty-six hours; vaccination performed at three different times

vesicle, which at length terminates in a concretion, and forms a crust. The stage of varus, or the papular, lasts but one day; the vesicular consists of four days *umbilicated*, and three *acuminated* and pustular: the process of incrustation is also three days more; so that allowing three days for incubation, the whole duration of the disease, from the time of puncture until the formation of the crust, is from fourteen to seventeen days; but some days elapse after this before the crust or scab falls off. The eighth day is the period of the first blush of the areola; this enlarges on the three following days, or those of pustulation, which is also the period of slight fever.

Anatomically considered, the vaccine pustule has its seat in the muciform tissue of the cutis, and is a little more superficial than the small-pox pustule, which has its seat in the thickness of the dermis. At its origin, it is only a small tubercle, more or less hard, but when most perfectly organized, bisect, either horizontally or perpendicularly, a pustule, and it will be seen divided into a number of cells, separated from each other by a thin cellular tissue, each filled with a clear diaphanous liquid, which is the vaccine virus. The cells do not communicate together, but radiate from the circumference to the centre, where they unite in a common bride, which depresses the cuticle and gives the umbilicated character to the pustule. This is the state of the parts from the sixth to the ninth day—but it does not last, the lymph becoming altered and turbid, and pus mingles with the virus, the bride is broken, and the pustule ruptures. There are many anomalies in the form and character of the pustule. This latter we should regard as an external sign of a constitutional disease, but not necessary to it.

The vaccine cicatrix is round, deep, puckered, radiated, and studded with points, which answer, without doubt, to the cells into which the interior of the pustule is divided. It is more marked in proportion as it is more recent; but it is never entirely effaced by time. The cicatrix is not to be received as an infallible criterion of the actual amount of constitutional protection, although, in the existing state of our knowledge, it is the best.

<sup>1</sup> Baker.—Obs. sur un bouton vaccin développé six mois après l'insertion du Virus. Arch. gén. de méd., t. 1. p. 277.

<sup>2</sup> Rapport du comité de vaccine, 1812.

subsequently produced neither eruption nor fever; inoculation of small-pox was also performed in vain. M. Bousquet gives several analogous facts, which must be distinguished from the simple febrile paroxysms produced by the punctures.<sup>3</sup> In cow-pox as in small-pox, the *general infection* is the essential matter; the eruption is merely secondary.

483. Cow-pox is a very mild disease; but it may accidentally be complicated with other affections. When the pustules are extremely numerous, inflammation of the axillary glands, eczema, accidental pustules, roseola, erysipelas, phlegmon, and inflammation of the lining membrane of the bowels, are the diseases that most frequently complicate cow-pox in children.

The direct inoculation of cow-pox has also been known to occasion the same complications in adults.

Of all possible complications, however, that of small-pox with cow-pox is the one which is fraught with the highest interest.<sup>4</sup> These eruptions most commonly modify each other when the two contagions exert their influence at the same time.<sup>5</sup> Yet it would appear that, under certain circumstances, the variolous contagion is not modified in its effects. (§ 500.) Thus at Marseilles, during the month of June, 1828, nine persons died of small-pox during the development of cow-pox, and three others had, previously to the above date, died under the same circumstances; in the month of August two more died, and in September two more, in all sixteen individuals, who became the victims of small-pox, in spite of cow-pox, which accompanied it.

When a mixture of the variolous and vaccine virus is inoculated, two different eruptions are occasionally developed perfectly in accordance with the twofold and dissimilar nature of their exciting cause. Woodville was the first who made this experiment, which has been repeated by Messrs. Salmade and Bousquet.<sup>6</sup> In opposition to the opinion of the latter, I conceive that the action of the variolous virus was modified in his experiment, and that the eruption which *left no cicatrices* was rather the umbilicated pustular varicella than legitimate variola.

484. Professor Monteggia,<sup>7</sup> in a paper read on the 17th of February, 1814, before the Institute of Milan, maintained that if a syphilitic child were vaccinated, a pustule was developed which contained the two poisons. In 1821, M. G. Cerioli again advanced the same opinion: "Catterina Selibino, two months and a half old, healthy to all appearance, was vaccinated. The vaccine pustule became perfectly well developed; on the 16th of June, 1814, ten children were vaccinated with the lymph from her arm, and with the virus from these ten, thirty other children were inoculated. Within a few months Catterina Selibino and five of the first vaccinated children died. Of the thirty vaccinated in the second instance, only seven could be traced. Of these, one was seized with a peculiar disease which he communicated to his brothers, and another also exhibited morbid symptoms. The parents of Catterina had long laboured under a syphilitic complaint which they neglected. A few days after the vaccination, the child became covered with pustules, which appeared upon the external parts of generation, about the anus, on the neck, forehead, and around the mouth. The other children vaccinated were attacked with similar pustules, ulcerations of the mouth, and morbid growths about the arms; the disease was also communicated to several nurses, who suckled these infants, and to different other children who were nursed along with them."

485. *Diagnosis*.—Cow-pox is not liable to be confounded with the accidental pustules which have very improperly been designated *false cow-pox*, and which are produced every time that pus or another stimulating fluid is inoculated. Such pustules are evolved on the morrow, or the day after that, on which the operation was performed; they are circular in their shape, and rise into a point from the period of their evolution; their summits are yellowish, and they are so fragile

that they give way under even the slightest pressure; the pus they contain escapes and dries up from the third to the fifth day. The scabs that succeed are yellow, soft, and often bathed in an ichorous fluid. In a word, these pustules have neither the course nor the umbilicated appearance characteristic of those of cow-pox.

*Vaccinella* or *spurious* cow-pox bears a greater resemblance to cow-pox, the disease being characterized by the presence of one or of several pustules, accurately circumscribed and umbilicated, which, like those of the true cow-pox, appear on the fourth day, advance like them, although with an inferior degree of attendant inflammation, to the eighth or ninth day, and usually dry up about the fourteenth or fifteenth day. The fluid they contain, if inoculated, is capable of producing the legitimate cow-pox (Eiehorn), as well as a pustule, which differs from true vaccinia, either in the greater rapidity of its progress, after it has attained the period of suppuration, by being accompanied with a less degree of inflammation either of its circumference or of its areola, and by being followed by a mere mark or very slight scar instead of the pinked and puckered cicatrice characteristic of true vaccinia; lastly, the pustules of *vaccinella* do not so certainly preserve from variola as those of cow-pox.

In the various particulars of their form and progress the pustules of cow-pox have the greatest similarity to those of inoculated small-pox. Like these they are evolved several days after the insertion of a peculiar virus; like them they are of a circular shape, pitted in the centre, and pass through their periods in the course of about three weeks; but they differ in the circumstance of their contagion not being transmitted like that of small-pox by the medium of the atmosphere. The eruption of variola is also essentially of a general nature, whilst that of vaccinia, with the exception of a very small number of cases, is purely local. Despite their common features, however, these two diseases seem to be even mutually opposed; their simultaneous inoculation very commonly induces modifications in their outward appearances and in their progress. It has been said, indeed, that the virus of small-pox inoculated upon the common heifer produces cow-pox; but the experiment has been repeated without such a result.<sup>1</sup> Dr. Sunderland<sup>2</sup> has also been said to have succeeded not only in giving small-pox to a heifer by clothing it with the coverlid of a variolous patient's bed, but in successfully using the matter of the eruption thus produced for engendering cow-pox in the human subject; Dr. Numan, however, on repeating this experiment, did not obtain the same results.

The researches of M. Guillon have demonstrated the analogy of the umbilicated pustular varicella when produced by inoculations, to cow-pox.

Vaccinia being the product of the virus of cow-pox transplanted upon the human subject, it can be no matter of astonishment that the two eruptions in man and the animal should resemble each other, nor that the virus of the vaccinia of man inoculated upon the teat of the cow, should there occasionally produce cow-pox.

The matter of the small pustules of the *grease* of the horse, inoculated upon man, or the cow, has been said to cause the development of vaccinia or cow-pox,<sup>3</sup> but the experiment was repeated by Woodville, Simmons, and Buniva without any such consequences. Several of the cases of *grease* which have been shown to me by well-informed veterinary practitioners, belonged evidently to eczema impetiginodes, or to impetigo. (a)

(a) I cannot better present the subject of the probable origin of cow-pox and of its connection with small-pox, than by repeating the brief summary which I have recently made in another work.

"The original source of vaccine virus was believed by Jenner to be in the heel of the horse when this animal is affected with the disorder called grease. Experiment and analogy are, however, opposed to this view. Another hypothesis of Jenner has been revised of late years, and apparently its reality confirmed by experiment. He expressed 'his unalterable conviction that how different soever they might be in some particulars, the cow-pox and the small-pox were in reality identical;' that the cow-pox was not 'an antidote but the

486. *Prognosis*.—Vaccinia attains the height of its preservative power on the second day of its appearance.

M. Bousquet has shown that the integrity of the pustules was not required to give vaccinia its preservative virtues; he opened and cauterized the pustules from the moment of their appearance, and vaccination performed anew was without effect.

Not only is cow-pox generally a complaint of extreme mildness, but in certain circumstances it may even prove a kind of *salutary disease*. Like several other forms of external inflammation, it has occasionally brought about or hastened the cure of ophthalmia, otitis, chronic bronchitis, and whooping-cough; further, its virus inserted into various chronic inflammatory affections of the skin, may accelerate the progress of these affections.

substitution of a mild species of small-pox instead of a malignant sort, or of cow small-pox for human small-pox.' Trials were made to test this hypothesis; but although many cows have been clothed with blankets taken from the bed on which small-pox patients had just died, and have been inoculated in every possible way, yet, not only has this small-pox not been satisfactorily produced, but this failure of such experiments rendered it probable that the cow was unsusceptible of the disease.

"Of late years the question has assumed a new aspect since the success of Mr. Ceely's trials, by inoculating the cow with variolous virus, and procuring from the pustules matter which, introduced into the skin of the hitherto unprotected human subject, gave rise to distinct vaccinia and allowed of successive transfers to other subjects, with the preservation of all the regular features and other phenomena of the cow-pox. Mr. Fare, in his letter to the Registrar-General of England, in the annual report for 1842, adopts, as a received truth, these results, when he says, *varioline*, or the specific matter of small-pox, is converted into vaccine. It had been asserted in 1828 by Dr. McMichael, in an essay read before the College of Physicians, that 'vaccine matters having failed in Egypt, medical gentlemen were led to institute certain experiments by which it has been discovered that, by inoculating the cow with small-pox from the human body, fine active vaccine virus is produced.' Connected with this question are the interesting facts on record, of the prevalence, at the same period, of the cow-pox among cattle and the small-pox among men, and the transmission by contagion of the small-pox to cattle, and the consequent development of cow-pox in these animals.

"If we are to speak of the habits of the *vaccinæ* or vaccine poison as seen in the cow, we learn that the disease is occasionally epizootic or prevalent, at the same time, at several farms at no great distance from each other, but that more commonly it is sporadic, or nearly solitary. So irregular is its appearance, that Mr. Ceely (*On Variolæ Vaccinæ*), states that he has known it to occur twice in five years, in two contiguous farms in Buckinghamshire; while at a third adjoining dairy it had not been known to exist for forty years. It is said to appear most commonly about the beginning or end of spring, rarely during the height of summer, but has been seen at any period from August till May, or the beginning of June. One other remarkable circumstance, however, connected with the disease in the case, is that it is peculiar to some countries, and to certain districts of the same country. On the first publication of Dr. Jenner's discovery it was much sought for in England, but found to exist only in eighteen counties. It has been found, also, among the cattle of Lombardy, Holstein, Persia, the southern parts of America, and in India. It is singular, however, continues Dr. Williams, whose narrative I am now following, that it was altogether unknown in France till 1836, when, by an inexplicable *bizarrie*, it was discovered in three separate districts, at a short distance from each other, or at Passy, near Paris, Amiens, and at Rambouillet. This latter fact is strong argument against the disease being small-pox, and of the cow being affected by the human subject, for on such an hypothesis it is impossible to assign any reason why the disease should be so often communicated in England and so seldom in France. The poison is capable, also, of producing the cow-pox in many animals, not naturally liable to it by vaccination, as the dog, the goat, the she-ass, the sheep, and, perhaps, the horse." *Bell and Stokes's Lectures on the Practice of Physic*, 3d edit., p. 735, vol. ii.

<sup>2</sup> Arch. gén. de méd., Nov. 1831.

<sup>3</sup> Loy. Acci. of some experiments on the origin of cow-pox, 8vo. London, 1820.

The detractors from the merits of vaccine inoculation on the other hand, have said, but without proving their assertions, that phthisis, rickets, scrofula, nervous fever, &c., have become much more frequent in Europe since this eruption has been made to replace that of small-pox.

487. *Treatment*.—Cow-pox, uncomplicated with any other co-existent affection, requires no treatment; it ought to be left to itself, in order that it may run through its natural periods unimpeded. The pustules should be preserved from all rubbing and compression which might injure them before the period at which the virus they contain may be collected for other vaccinations. The custom of giving an aperient after the fall of the scabs, so generally insisted on by mothers and nurses, is seldom necessary.

488. Should roseola, (§ 269,) a large phlegmon, extensive erysipelas, acute inflammation of the axillary glands, &c., complicate vaccination, these various affections must be subdued by blood-letting, low diet, and the other measures usually adopted in their treatment. Should the development of too large a number of pustules appear to occasion unpleasant symptoms, one or more of the points may be touched with caustic, and their progress thus arrested without the protecting influence of the others being injured by the practice.

489. It has been said that the vaccine virus has *degenerated*, and that of late years the eruption has not been so vigorous as it was of old; that the vaccine fever is less marked, and the cicatrices not so definite; that the disease can no longer be transmitted back to the cow; that small-pox occurs more frequent after vaccination now than formerly, and that we also succeed more readily in giving cow-pox twice to the same individual. In the expectation of finding a remedy for this presumed degeneracy of the vaccine virus, it has been proposed to recur to the matter of cow-pox developed spontaneously in the animal, or to the virus tempered anew in its source by being transferred from man to the cow.<sup>1</sup> (a)

490. These fears, however, appear exaggerated at least. It is certain that we every day meet with vaccine pustules which resemble in every particular those, the description of which have been transmitted to us by the earliest vaccinators, several of whom, and Marshall in particular, inform us that persons vaccinated, may go about their ordinary business. The assertion in regard to the cicatrices is entirely gratuitous. It has at all times been found a difficult matter to inoculate the cow with the vaccine virus. The occurrence of small-pox after vaccination appears more frequent at the present day only because

(a) Means of comparison in this respect, within the last four or five years, have been furnished to the profession in England, and measurably to some physicians in the United States, chiefly through the labours of Mr. Estlin, of Bristol; but as yet the question is not clearly settled. The few trials made by myself do not incline me to give a preference to the vaccine virus recently procured from the cow; or to *retro-vaccination*, as it is called. We have no evidence of its greater protecting power, although generally the inflammation is greater and the areola larger than in vaccinia induced by the older transmitted matter. Upon the whole, however, we are justified,—and, considering the possible causes of deterioration of the vaccine matter in its transmission through a great succession of persons, perhaps we should add, authorized—to recur to the primary lymph from the cow.

The following curious fact, if it be a fact, is worth mentioning in this place. I find it in a note at p. 116 of Mr. Wilson's book.—*Am. edition.*

"Dr. Lichtenstein, in a paper, entitled 'on the sources from which matter preservative against the small-pox has been derived,' in Hufeland's Journal for 1841, remarks, that limpid lymph taken from the pustules produced by tartarized antimony, and inoculated in a person who has not been vaccinated, produces vesicles, which cannot be distinguished from those of vaccinia. These vesicles appear to be equally protective against small-pox with the cow-pox, and the matter may be transmitted from person to person in the same manner. The author has inoculated and re-inoculated thirty-one persons with the matter procured from this source; and these persons were protected during an epidemic of small-pox, although placed in association with patients affected with that disease."

<sup>1</sup> Fiard. Nécessité de régénérer la vaccine (Rev. Méd., 2de série, t. ii. p. 323.)

the fact is no longer disputed, and perhaps because variolous medical constitutions have been more than usually prevalent of late. Lastly, the possibility of communicating cow-pox a second time, twenty years after its first inoculation, so far from proving that the vaccine virus at our disposal in the present day is less energetic than it used to be, tends rather to demonstrate the reverse of the proposition. Nothing, then, shows that *cow-pox has degenerated*.

491. In the event of a variolous epidemic, it is well to vaccinate anew all who may have had the operation already performed, but who possess no certificate or assurance of their having previously passed regularly through the different stages of cow-pox.

Several practitioners having thought they perceived that those among the vaccinated who had had the operation performed most remotely, were more subject to attacks of variolous eruption than the rest, have proposed to re-vaccinate the same individual at intervals of a year, two years, seven years, &c. For my own part, I conceive that vaccination ought to be attempted as often as a variolous epidemic prevails, or at least on occasion of the first epidemic of this kind that follows the vaccination, when the operation has not been performed in the way proposed by Eichhorn. (a)

(a) Overweening confidence, as I have elsewhere remarked, in the all-protecting power of vaccination against small-pox was followed by undue mistrust of its efficacy. Physicians had too generally forgotten, that Jenner himself, and some of his zealous cotemporaries engaged in the same philanthropic task with him, had clearly pointed out the fact of small-pox supervening after vaccination had been duly performed. The reason assigned then was the shortness of time that had elapsed between the vaccination and the exposure to variolous contagion. Since, and now, the reason set forth is the length of time, by which the vaccine impression on the system is worn out. Both of these two opposite and contradictory reasons cannot be true—the probability is, that neither rests on a stable foundation.

"In the two papers which I wrote exhibiting the joint experience of Dr. J. K. Mitchell and myself, we concluded with the following inferences, the accuracy of which has been tested by succeeding observations in different parts of Europe, and of this country. The first inference was, that the disease which prevailed in Philadelphia, in 1823–4, and which we had been called upon to treat in so large a number of cases, was the real small-pox.

"2. That this disease, distressing to the persons labouring under it, and disgusting to those in attendance, is usually violent, never without danger, and always in large proportion, under any known treatment, is of fatal termination.

"3. That the unsusceptibility of persons who have once had the small-pox to a second attack, though of general notoriety and truth, is not universal, and that with us, as elsewhere, persons, thus apparently protected, were seized with the disease, of which some of them died.

"4. That inoculation of small-pox, though in general conferring on the person subjected to this process immunity from the effects of variolous contagion in after life, does not necessarily or infallibly guarantee him against the disease, nor prevent death when it has made its invasion.

"5. That vaccination cannot now, any more than on its first introduction, be received as a certain preventive against the effects of the variolous poison, though now, as formerly, it must be considered as the best and safest with which we are acquainted.

"6. That occasionally under all circumstances of exposure, but more especially during the epidemic prevalence of small-pox, its contagion will effect both the inoculated and the vaccinated, and produce in them a fever and eruption, differing in no essential feature from the primary variolous disease, except in the general mildness and speedier subsidence of the cutaneous disorder, and the more common exemption from secondary fever.

"7. That, of the inoculated and the vaccinated exposed to the variolous poison, the former will more probably escape its influence than the latter; but if both be affected by this contagion, the chances of recovery are in favour of the vaccinated.

"8. That the protecting power of the vaccine virus on persons who have been duly subject to its influence, is not diminished nor

492. Since Jenner made his discovery, variolous epidemics have desolated various quarters of Europe, and the vaccinated themselves have not escaped their ravages. Dr. Eichhorn has made a particular study of these epidemics, and has deduced the following conclusions from their different histories: 1. The vaccinated may have *legitimate* as well as *modified* small-pox, and they generally suffer more severely in proportion as the number of vaccine pustules has been smaller. 2. Among all who have been vaccinated up to the present time, not more than the half have been protected from all attack, slight or severe, of small-pox. 3. The ratio of *modified* (varioid) to *true* small-pox after vaccination, is very various; it is milder or more serious in proportion as a greater or a smaller number of vaccine punctures have been made.

The vast importance here attached to the number of vaccine pustules engendered, is a point that has been disputed; I have seen individuals labouring under *modified* small-pox whose arms were marked with four or five vaccine cicatrices, but my observations are not sufficiently extensive to warrant me in drawing any general conclusions in opposition to those of Dr. Eichhorn.

destroyed by the length of time from its first introduction into the bodies of such persons; and that no proportion whatever exists between its efficacy and the recency or remoteness of the epoch, when the constitution was placed under the influence of the virus.

"9. That there is no reason for believing in the deterioration or alteration of the vaccine virus, which is used at this time, from that which was in use during the first years of the practice of vaccination.

"The data on which we based the above conclusions were observations of 248 cases of natural and modified small-pox, of which 176 were visited at the hospital. Of these there were—

Unprotected.	Vaccinated.	Inoculated.	Prev. Small-Pox.	Unk.
155	64	9	7	13
Deaths 85	1	3	3	—

In regard to colour the proportion was—

Whites, total.	Whites unprotected.	Col. persons total.	Id. unprotect.
111	60	122	91
Deaths	31		54

"It is pleasant to find, after a period of enlarged experience of fifteen years, these opinions of ours so fully sustained by the conclusions of the French Commission of Vaccine, made in 1839.

"1. That the simultaneous vaccination of the mass instantly arrests the progress of the variolous epidemic.

"2. That if vaccinia be not an absolute and infallible preservative against variola, it is at least the most certain, and the most exempt from danger.

"3. That varioid, in the majority of cases, is the only inconvenience to which the vaccinated are exposed.

"4. That there seems no reason for the belief that the long vaccinated are not as surely preserved at the present day as they have hitherto been; or that the recently vaccinated have received less security than those who preceded them.

"5. That the complete success of re-vaccination affords no proof that the individual had ceased to be protected by vaccination, and that he had again become susceptible of variola.

"6. That a second vaccination does not appear to possess the power, any more than the first, of protecting all persons indiscriminately from the risk of a future attack of variola.

"7. That government ought not to command a general re-vaccination.

"8. That the total extinction of variola is to be effected by the universal adoption of vaccination.

"I am well aware, that of late years re-vaccination has been practiced on a large scale on the soldiers in the armies of Prussia and Wirtemberg, as well as on the people, and with such results as would seem to weaken a belief in the continued protecting power through life of the first vaccination—but other and different testimony leave us nearly free to retain our first belief, with the explanations already offered."—*Bell and Stokes's Lectures on the Practice of Physic*, 3d edit., p. 737, vol. ii.

### Historical Notices and particular Cases.

493. Jenner published his "*Inquiry into the causes and effects of variola vaccina*," in 1798,<sup>1</sup> and his admirable discovery spread rapidly over the whole of Europe. Mr. W. Bruce,<sup>2</sup> Consul at Bushire, in a letter dated March, 1813, tells us that the preservative powers of the vaccine pustule were perfectly well known among the nomadic tribe of the Eliaats.

Cow-pox has been the subject of very numerous inquiries (vide Appendix, art. cow-pox). Jenner himself imagined that it arose from the grease of the horse; an opinion which has been successfully combated by Pearson, Simmons,<sup>3</sup> and Buniva.

Besides the excellent treatises of Messrs. Husson,<sup>4</sup> Sacco,<sup>5</sup> and Bousquet,<sup>6</sup> the reader ought to consult the several essays and observations which have appeared on the *identity* of small-pox and cow-pox,<sup>7</sup> on the *period at which cow-pox becomes preservative*,<sup>8</sup> on the *multiplicity* of the pustules of cow-pox,<sup>9</sup> on the *fever of incubation* of cow-pox,<sup>10</sup> on the *influence of cow-pox appearing to extend from the mother to the fetus* during pregnancy,<sup>11</sup> on the *ANOMALIES* presented by cow-pox,<sup>12</sup> on its *complications*,<sup>13</sup> on the *attempts to inoculate with small-pox, individuals already vaccinated*,<sup>14</sup> and on the *reciprocal influence* of small-pox and of cow-pox.<sup>15</sup>

The remarks which have been published on modified small-pox, (§ 503,) on the salutary influence of vaccine-pox in *whooping-cough*,<sup>16</sup> on *quartan ague*,<sup>17</sup> on *ophthalmia*,<sup>18</sup> on *gout*, &c.,<sup>19</sup> all deserve to be consulted as well as those that have been made, on its influence on the ratio of mortality,<sup>20</sup> on *repeated vaccination*,<sup>21</sup> on the development of legitimate vaccine-pox in individuals who have had small-pox, &c.<sup>22</sup>

Lastly, several interesting experiments have shown that the vaccine infection could not be prevented by applying cupping glasses,<sup>23</sup> aqua ammoniæ,<sup>24</sup> or lotions containing solutions of the chlorates to the punctures immediately after the insertion of the virus. Different plans of collecting the vaccine virus have been proposed,<sup>25</sup> and various attempts have been made to infect the cow and other animals with the disease, by inoculating them with the virus of vaccinia<sup>26</sup> and of small-pox.<sup>27</sup>

<sup>27</sup> Expériences de Sunderland et de Numan. Bull. des sc. méd., t. xxv. p. 158.

October, M. Hamel vaccinated a lady, thirty-four years of age, who had never had the operation done before, and who did not remember having ever had the small-pox. Towards the end of the fourth day following, he found two red spots in the situation of his punctures, about a line in diameter, and depressed in their centre, which, continuing to advance, presented in regular succession the whole of the characters of regular vaccinia. A sister of this lady, twenty-two years of age, who had been vaccinated when two years old, was present at the vaccination, and although she bore two very distinct cicatrices upon the upper part of each arm in the situation where vaccination is usually performed, she desired that the operation might be done again. M. Hamel consequently made six punctures in either arm, from which he anticipated no effect. On the fourth day, however, he was surprised to find a single point (all the others had faded) on the right arm inflamed, and forming a spot about a line in diameter, depressed in the centre, and similar to those by which the success of vaccine inoculation is usually proclaimed. By the end of the seventh day the pustule was perfectly characteristic of vaccinia; its centre was depressed, its margin was raised and transparent, and it was surrounded by an inflamed areola of small extent. At the end of the eighth day the pustule was still more fully developed, and the inflamed areola broader. The parts in the neighbourhood of the pustule were itchy; the young lady complained of being indisposed; the glands of the axilla were slightly inflamed. On the ninth day M. Hamel related the case to me, and on the tenth day I had an opportunity of seeing it along with him, when I found a perfectly regular vaccine pustule; the fluid it contained had by this time lost its transparency, and presented the peculiar appearance which announces approaching desiccation.

One of the cicatrices of the former vaccination was circular, depressed, and pinked (gauffrée) like the cicatrices which result from the most regular vaccine pustules. It was three lines in diameter. A second cicatrix on the right shoulder had also the same characters, but was different in shape, apparently from the fusion of two pustules into one. The young lady left Paris on the 19th day, the vaccine incrustation still adhering.

CASE LXXIII.—*Vaccinia in an individual successfully inoculated for small-pox thirty years before, and bearing on his person several characteristic cicatrices.* The Prince de \* \* \* \* had been inoculated in England in his infancy; the operation succeeded, and the eruption was held protective. Happening, in 1833, to be present when I was re-vaccinating another individual, the Prince proposed that I should make a few punctures on his arm with a lancet charged with vaccine virus. The operation was succeeded by the most regular cow-pox, a fact which was attested by several competent witnesses.

#### VACCINELLA OR MODIFICATIONS OF VACCINIA.

Vocab. *Vaccinellæ, Vaccinæ spuria, Spurious Cow-pox.*

494. Under this title I include several pustular inflammations of the skin, contagious in their nature, and similar to cow-pox in their appearance, which the inoculation of the vaccine virus or of the virus of *grease*, according to some accounts, occasionally produces in individuals who have previously had small-pox or vaccinia, or who only contract the latter malady imperfectly, either from want of sufficient energy in the vaccine virus, or from a kind of inaptitude to feel its effects; I also employ the same word to designate those modified vaccine eruptions which are thrown out after vaccination during the period of incubation or of the primary fever of small-pox, and to those which often proceed from the simultaneous inoculation of cow-pox and small-pox. These eruptions in fact are to vaccinia precisely what the varicellæ are to variola.

It is necessary to distinguish those eruptions, the matter of which possesses the power of reproducing vaccinia (Eichhorn), from certain accidental and non-contagious pustules which have also been described under the name of *spurious cow-pox*, and which seem to result either from the matter of cow-pox altered and deprived of its peculiar virulence, or from the inoculation of good vaccine matter upon constitutions which have become callous to its proper influence, in con-

sequence of a previous preservative variolous or vaccine infection. Several eruptions, transmitted to the human subject from the cow attacked with spurious cow-pox, or from the heel of the horse labouring under grease, might, perhaps, without impropriety, be also classed in this group.

495. 1st. *Vaccinella from the inoculation of individuals with vaccine virus who have already had vaccinia.*<sup>1</sup>—This variety has been observed by several practitioners who have re-vaccinated a large number of subjects. M. Bousquet says, that in one case which he met with, this second cow-pox advanced at a more rapid pace than the first, and that there was the same difference between the two eruptions that is observed between small-pox and varicella.

496. 2d. *Vaccinella from the inoculation of vaccinia upon individuals who had previously had natural or inoculated small-pox.*<sup>2</sup>—When persons who have formerly had small small-pox are vaccinated, the operation is usually without effect. Occasionally, however, a vaccine eruption, modified in its external appearances, and in its progress, is excited. This result cannot be more aptly compared than to the varicella which the variolous poison produces in some vaccinated individuals, or to the eruptions observed among the inoculated or small-poxed, who are submitted to a fresh inoculation of the variolous virus. However this may be, the progress of this modified vaccinia or cow-pox is as follows:

From the first, occasionally on the second, and at latest on the third day, the punctures inflame, and pustules, most commonly of a circular shape like those of cow-pox, are formed. Their margins are flat, irregular, and not distended with fluid, which is always scanty, and of a pale-yellowish colour. The areola, occasionally as bright, is rarely so broad as that of vaccinia, although it appears at any earlier period. During the whole time this process is going forward the punctures and then the pustules are affected with an insupportable pruritus; the axillæ are occasionally painful, and the axillary glands become enlarged; headache is also felt at times, or irregular febrile paroxysms intervene. The inflammatory period is very rapid; there is no tumour nor circumscribed induration as in regular vaccinia, and if some degree of puffing be felt around the puncture it is irregular and superficial. The scabs, well formed from the seventh or eighth day, are detached nearly at the same period as those of vaccinia, and occasionally sooner. They often present the same appearances, with this single difference, that they are not so large nor so thick, and that they do not leave cicatrices, but merely marks on the skin. The fluid of the pustules is contagious, and inserted under the skin by a puncture; the disease can be propagated like legitimate vaccinia, but without proving preservative in the same degree against small-pox.

497. 3d. *Vaccinella from the accidental inoculation with cow-pox of an individual who had had small-pox.* Jenner relates<sup>3</sup> that he saw five persons on the farm of Mr. Andrews, who after having had small-pox, contracted cow-pox from milking kine affected with this disease. But he adds, that the eruption was incomparably milder than it commonly proves.

498. 4th. *Vaccinella from the simultaneous inoculation of variola and vaccinia.*<sup>4</sup> When the variolous and vaccine virus are inoculated as nearly as possible at the same time, they reciprocally modify each other's action. The vaccine pustule produced under these circumstances appears like, but somewhat smaller in size than that of the natural vaccinia upon the fourth day after the inoculation; on the seventh and eighth days the areola is scarcely perceptible, and on the ninth and tenth no true vaccine tumour is formed. On the other hand the inoculated variola is itself modified in its characters, and appears with the features of the umbilicated pustular varicella.

499. 5th. *Vaccinella from the insertion of vaccinia during the incubation of the variolous contagion or the period of the precursory variolous fever.* Many cases have been related of vaccinia modified by small-pox, either in its external characters or in its duration. In a case which I have just seen at La Charité, cow-pox is developed in

<sup>2</sup> Rapport de la commission médico-chirurgicale instituée à Milan, 8vo. Paris, an. x.

<sup>3</sup> Op. cit.

<sup>4</sup> Willan on vaccine inocul., 4to. Lond. 1806.

an individual who has already felt the influence of small-pox contagion. (The elevations of small-pox appeared at the beginning of the seventh day from that of the vaccination, after four days of initiatory variolous fever, and at least eight if not ten days after exposure to small-pox infection.) The vaccine pustules had their usual duration; they were only not accompanied on the seventh and eighth days with that degree of inflammation which produces the hardness, known under the name of the *vaccine tumour*.

CASE LXXIV.—*Vesicular varicella* (chicken-pox); *vaccination and development of vaccinia*; *appearance of small-pox on the seventh day of the vaccination*. P. M. Dufeu, 33 years of age, presented himself for admission into La Charité, on the 9th October, 1833. He was in the third day of an eruption of vesicular varicella, the precursory phenomena of which had been extremely slight and had only lasted six and thirty hours. The patient was without fever; the eruption was scanty and looked shrunk in many places, in which small red spots irregularly rounded, were perceived, covered in the centre with a slight scab, or incrustation of dried blood. Under the clavicles, and in the axillary spaces the eruption preserved its primary character. It consisted of vesicles a little larger than hemp seeds, of a rounded figure, very prominent, widely scattered and filled either with a transparent or an opaline fluid. Each of these vesicles was surrounded by a red areola of a diameter the double of itself. October 12th.—The shriveled vesicles had lost their transparency, and several of them which had been ruptured by the friction of the clothes were covered with a small brownish scab. On the 17th the recovery was complete.

Small-pox, at this period, was rife in Paris, and several of the patients in La Charité were attacked. This patient not appearing to have been vaccinated, or at least having no variolous or vaccine cicatrices about him, I had the operation done at the Royal Academy of Medicine on the 19th of October; three deepish punctures were made on the inner aspect of both arms.

October 20th and 21st, a small bloody point showed the spot where each of the punctures had been made. 22d.—Third day of vaccination; the patient, towards evening, felt feverish; the appearance of the pustules had not changed. 23d.—Headache, nausea, higher fever; the punctures are slightly prominent and surrounded by a red circle. (*Low diet, lemonade, foot-bath.*) 24th.—Headache worse; nausea incessant. The vaccine elevation, which is readily distinguishable, has not enlarged; in its centre a point of a pale rosy hue is perceived, veiled by the epidermis. 25th.—Same general phenomena. The vaccine pustule larger this day than yesterday, is of a bluish-white colour; its centre is slightly depressed. The areola is not more than a line in breadth. Same treatment continued. The patient revaccinated. 26th.—Seventh day of the vaccination; the patient is freer from headache and fever. The vaccine pustules are small, not being more than two lines in breadth, and are but slightly prominent.

This almost entire cessation of the febrile symptoms coincided with the appearance of a new eruption which I remarked at the morning visit. A considerable number of small, red, and slightly prominent spots, the size of flea bites, several of which were in contact at their edges, had appeared upon the face, and in smaller numbers on the breast and arms: small-pox, as I have said, was prevalent; four days of febrile symptoms had preceded the appearance of the eruption: I had no hesitation in deciding on the variolous nature of this eruption. 28th.—The eruption is confluent on different parts of the face; some of the pustules have already assumed the umbilicated form; several are evolved on the very circumference of the vaccine pustules with which they cohere. The areola of the latter is not more extensive than before; it is of a bright enough colour, but of little breadth.

30th.—The small-pox pustules in the neighbourhood of those of the cow-pox, resemble them so closely that it would be impossible to distinguish the one from the other, had not the points upon which the vaccination was performed been particularly noted. The desiccation is commencing in their centre; there is no longer any areola properly speaking. The variolous pustules of the face have an opalescent look; the whole countenance is slightly puffed. 31st.—Slight epistaxis; some confusion of head, and wandering of ideas. November 1st.—Unequivocal symptoms of secondary fever; pyalism; rambling talk; heat of surface, &c.; the swelling of face continues; the pustules are flat and umbilicated on the arms, globular on the face. 2d.—The

vaccine pustules are covered with yellow crusts; several of the variolous pustules of the face begin to dry; the pulse is pretty full without hardness or frequency. 3d.—The pustules of the trunk and limbs are in full suppuration. 5th.—Both vaccine and variolous pustules are drying apace. 6th.—The face is fully incrustated, and from the 7th to the 11th, the drying and fall of the scabs proceeded on the other parts of the body. The crusts of the vaccine pustules were not detached till the 9th of November (22d day of the vaccination). They left red marks behind them without distinct depressions.

500. It would appear, that a kind of spurious cow-pox may be developed on the teat of the cow, and be transmitted to man by contagion. The degree of analogy which these false cow-pox bear to the true account of which is blended by Willan and Bateman with that of rosa disease, and which these false cow-pox transmitted to the human subject bear to vaccinia, is as yet ill ascertained. The eruption observed by Loy,<sup>1</sup> has no apparent resemblance to vaccinia. In the beginning of 1801, this writer saw an eruption on the hands of a farrier, which appeared shortly after having dressed the heels of a horse affected with *grease*. The eruption consisted of separate round pustules, like blisters produced by a scald, containing a limpid fluid, having a slight black speck in the centre, and being surrounded by an inflamed areola. During the whole course of this disease the man did not suffer from fever.

#### Historical Notices.

501. I have already signalized the principal characters which distinguish legitimate vaccinia from vaccinella (§ 485). These differ in the contagious nature and specific properties of the fluid they contain, and in the progress and form of the pustules, from those *accidental* pustules which have been improperly denominated *spurious cow-pox* or *spurious small-pox*, according as they have followed the inoculation of matter taken from the pustules of subjects who had previously been vaccinated or had had small-pox, in which the contagious and specific properties were extinct.

None of the varieties of vaccinella protect completely from small-pox; they however seem to render individuals less apt to contract the disease. They are always very mild complaints, and require no treatment.

502. Of all these eruptions, one only has been studied with particular attention; that, namely, which is produced by inoculating with vaccinia individuals affected with small-pox or already vaccinated. The other varieties of vaccinella have been rather hinted at than particularly described, and their history requires elucidation by additional experiments and researches.

M. Bousquet admits no more than a single species of spurious cow-pox. Nissen<sup>2</sup> recognizes two, proceeding from two different species of cow-pox (the one with *black* and the other with *amber coloured* pustules). Hellwag has described a third variety, characterized by vesicles filled with a yellowish and non-contagious serum; Viborg admits as many as nine species of cow-pox. By making the varieties of *spurious cow-pox* or *varicella* a particular subject of study, the counterparts of the different varicellæ may perhaps be detected. (Vide sub. cow-pox in vocab.)

According to Eichhorn,<sup>3</sup> re-vaccination occasionally produces legitimate and *unmodified*, but much more frequently *modified* vaccinia. The latter includes four varieties: 1. *Purulent* modified vaccinia; 2. *Lymphatic* modified vaccinia; 3. *Tuberculo-pustular* modified vaccinia; 4. *Tubercular* modified vaccinia. To each of these varieties he assigns particular characters.

<sup>1</sup> Loy. An account of some experiments on the origin of cow-pox, 1 vo. 1802.

<sup>2</sup> Kühn (C. G.). Op. cit. p. 13.

<sup>3</sup> Eichhorn admits four species of modified vaccinia, a title which he restricts to the eruption developed on the vaccinated by the inoculation of the true vaccine virus. He distinguishes carefully between *modified* vaccinia and *spurious* vaccinia, which, according to him, arises from the false cow-pox of the animal. He has re-vaccinated an immense number of individuals; 283 of the whole number remained unaffected, but among the rest, the four varieties of *modified* vaccinia specified in the text, were produced in various proportions. The three first of these, Dr. Eichhorn informs us, are capable of producing true vaccinia inoculated upon the unvaccinated. He was unable to prove that the fourth variety had the same property. Op. cit. p. 486.

## ACNE.

Vocab. *Acne*, *Ionthos*, *Varus*, *Whelk*.

503. *Ætius* in ancient, and *Sauvages* in modern times, employed the word *acne* to designate the red tubercles of the disease which we shall describe under the title of *Rosacea*. More lately, *Drs. Willan* and *Bateman* have included under this denomination, the *couperose*, the *dartre pustuleuse millaire*, and the *dartre pustuleuse dissimulée*, of *Alibert*. The term *couperose* (the *rosacea* or *gutta rosea* of English writers), being generally adopted in France to signify a chronic and pustular inflammation affecting the follicles of the skin of the face, I have felt myself compelled to use the word *acne* in a more restricted sense than that in which it was employed by the English pathologists, and to take it as indicative of the affection particularly described by *M. Alibert* under the title of *dartre pustuleuse dissimulée*, and which was blended with *couperose* by *Willan* and *Bateman*, under the head of *acne punctata*. Whilst I thus separately describe these two affections, I begin, nevertheless, by acknowledging that *acné* (the disseminated pustular tetter of *Alibert*) occurs under the same form, and affects the same elements of the skin as *rosacea*. I have, in fact, only consented to separate these two varieties, because the term *couperose* (*rosacea*) is applied in France to a very rebellious disease of the face, while *acne* is frequently an eruption attending adolescence, much less serious in its symptoms, and confined exclusively to the skin of the trunk.

In an anatomical point of view, syeosis, along with *acne* and *rosacea*, constitutes a third variety of one and the same form of pustular inflammation. The principal features which severally distinguish these three affections from each other, may be explained by the diversities of structure observed in the skin of the face generally, of the chin in particular, and of the trunk, especially as regards the number, disposition, dimensions, and depth of the sebaceous follicles of these different regions. (a)

*Acne*.—Under the title of *acne*, then, I shall describe a chronic inflammation of the sebaceous follicles common in youth and manhood, characterized by isolated acuminated pustules, most usually developed on the shoulders, sternal and scapular regions, the skin of which looks dense and unctuous, and more rarely on the face; these pustules are succeeded by livid or violet-coloured spots, by tuberculated indurations of the same, or of a milky-white hue, almost always intermingled with the accumulations of sebaceous matter with black points, vulgarly styled *worms*, and with follicular enlargements. (b)

(a) *Acne*, regarded as a genus by *Willan* and *Bateman*, is by them divided into four species, viz., 1. *A. simplex*; 2. *A. punctata*; 3. *A. indurata*; 4. *A. rosacea*—to which was subsequently added *A. syphilitica*. The first is *simple pimple*, the second *maggot pimple*, the third *stone-pock*; and the fourth *rosy drop* or *gutta rosea*.

(b) *Acne* by *Willan* and *Bateman* is placed among the *tubercula*, but by *Alibert*, *Bielt* and *M. Rayer* it is arranged with the pustular diseases of the skin. The latter is the correct view; the tubercles or circumscribed indurations, so constantly observed in this affection, being, as *Dr. T. J. Todd* (*Cyclop. Pract. Med.*) justly observes, the consequences of pustules, but not constituting the elementary forms of the eruption.

The peculiar seat of *acne* is stated by the author in the text, to be the sebaceous follicles; a location for the disease asserted by *Plumbe* to be its uniform one, and never, as some allege, the cellular texture of the corion. *Willan* had indeed made the follicular the character of his second species, or *acne punctata*; and by *Dr. Todd* it is called *follicularis*. *Plumbe* describes *acne*, syeosis, the scrofulous form of disease of the follicles, and lupus, or *noli me tangere* as four varieties of disease, depending on, or connected with obstructed and diseased follicles; while the pustules of the more obstinate forms of *porrigo* may be, he thinks, with propriety considered as the result of the local irritation of the hair.

"In its most simple and trifling form, the disease consists merely of obstruction of the sebaceous follicles, in consequence of their contents becoming too hard to pass readily to the surface. Inflammation of the follicle and the production of what is called a pimple result,

504. *Symptoms*.—The pustules of *acne* always appear in succession, one after the other. Usually scattered over the trunk, and occasionally over the face, the disease may be confined to the sternum and shoulders, or it may appear over the whole of these regions, and even extend to the posterior parts of the arms, to the cheeks and to the forehead. It is commonly evolved without heat or local pain, and very generally without pruritus. I have seen several young people seeking advice for a few spots of *acne* developed on the sternal region, whose backs were covered with the pustules of the disease, without their being aware of the circumstance.

Some of the pustules of *acne* are very small, others are a little larger. The first, at their origin, appear under the form of small inflamed and slightly conical elevations, the bases of which are hard and surrounded by a red blush or areola. These elevations suppurate slowly, and each pursues its course independently of the others around it; in the same individual, consequently, it is usual to find, at one and the same time, elevations not yet purulent, pustules in a state of suppuration, and others transformed into tubercles, or replaced by indurations of a milky-white colour, or by small cicatrices. The more voluminous pustules begin as follicular elevations or tumours full of sebaceous matter: either from over-distension or some other cause, the follicles themselves have become inflamed. By compressing the portion of skin surmounted by these pustules between the fingers, it is easy to ascertain that the stuff which can be squeezed from their summits is veritable pus; whilst the matter that remains within them, and which may also be forced out by continuing the pressure, is of a sebaceous nature, similar to that which is contained within the follicular elevations disseminated in the neighbourhood of the pustules. When the pustules begin to fade, their tops become covered with a small scab of variable thickness, which is soon detached, either spontaneously or by the friction of the clothes. Small spots of a livid-red, slightly elevated, and which disappear very gradually, proclaim at a later period the particular points which had been the seat of pustules. These are sometimes followed by small indurations of a milky-white colour, the size of a small pea, somewhat similar to the cicatrices that follow leech bites, although differing in shape. Lastly, the pustules of *acne* are often partially transformed into violet indurations, the resolution of which is generally looked for very long in vain. These tubercles are frequently of a violet-red colour, very analogous to that presented by such as are of a syphilitic nature. The tubercles of *acne* may, however, be distinguished from those of syphilis, by characters more positive than any that belong to colour, a class of signs, the value of which in diagnosis has been very much overrated by some pathologists.

In *acne*, the sebaceous follicles, besides being affected with suppuration, very commonly present three remarkable morbid phenomena; the orifices of the follicles of the skin of the back, shoulders, anterior part of the chest, and occasionally of the face are extremely apparent; the skin of the same districts is unctuous and shining; the pustules of *acne* are mixed with the concretions called *worms* indicated by more or less conspicuous black points, and formed by the accumulation of sebaceous matter within the follicles, from the cavities and ducts of which it may be extracted upon the point of a pin, or by pressure between the fingers. Further, the follicles of the sternal regions are occasionally hypertrophied in *acne*, and appear under the form of globular, or rounded and somewhat flattened bodies, not prominent, and of a duller white than the linear spaces of the skin which separate them. Lastly, small whitish and rounded granula-

and are soon followed by the formation of matter; the follicle is destroyed by this process, the matter is discharged, a little redness remains for a day or two, and the part returns to the healthy state."

"The situations in which the eruptions designated as above, make their appearance, will generally be sufficient to enable us to determine their character. It has been observed in a preceding page that the sebaceous follicles are chiefly distributed to the face, more particularly on the forehead, tip and alæ of the nose and the adjoining parts, and less copiously on the chin. Next to these the chest, below the clavicle, to about the fifth or sixth rib and the back to an equal extent, are most liberally furnished with them; and as the disease consists in the derangement and inflammation of these structures, it is these parts solely in which it makes its appearance." (*Plumbe, op. cit.* pp. 47-8.)

tions, the size of a pin's head and formed by follicles, the orifices of which are either very little or not at all apparent, are frequently observed among the pustules and sebaceous concretions, especially on the fore-part of the breast. In some individuals, these follicular elevations are more numerous than the pustules; in others the contrary disposition is observed to obtain. Thus several cases of acne compared together always show great variety in the disposal of the pustules or of the indurations left behind these, as also in the number of the sebaceous concretions and follicular elevations that occur.

Such is commonly the progress, and such are the appearances presented by acne. It is by no means rare to meet with this eruption associated with rosacea or sycosis, affections which occasionally replace it in maturer years. Several other inflammatory affections of the skin may accidentally occur in the course of acne without their appearing to exert any influence on its progress or termination. I have seen an adult affected at the same moment with acne, with herpes phlyctenodes of the face, trunk, and scrotum, and with pulmonary catarrh. I attended another young girl labouring under acne, herpes of the nose, and pulmonary tubercles; and an adult who presented a remarkable example of acne and chloasmata or liver spots of the skin.

The follicles of the scrotum, which are commonly very large, are occasionally affected with acne, precisely in the same manner as those of the upper part of the trunk. I have seen these follicles, distended with sebaceous matter, become transformed into pustules, from which the contents,—pus and sebaceous concretions, could be forced by squeezing them between the fingers. This change of the follicles of the scrotum is altogether independent of a venereal cause.

505. *Alterations of structure.*—The mode in which the pustules of acne are formed, the different morbid features that almost invariably accompany the disease, (*greasy state of the skin, sebaceous concretions, large size of the follicular orifices, &c.*) the enlargement of the follicles on those regions of the skin where the acne appears, the immunity from this disease enjoyed by those districts unprovided with sebaceous follicles, such as the palms of the hands and soles of the feet, are so many circumstances that authorize us in assigning the follicles as the element of the skin, which is particularly attacked in acne. This presumption, indeed, becomes matter of certainty, when the nascent and untouched pustules of the disease (or those which are older), after being laid open with the point of a lancet, are examined through a magnifying glass. Mr. Plumbe first satisfactorily demonstrated this anatomical fact; but he fell into an error, when he maintained that the inflammation of the follicles was always excited and kept up by the accumulation of sebaceous matter within their cavities. The whole of the pustules of acne certainly do not appear as sebaceous concretions, or follicular elevations at their outset; a certain number only commence in this way; the rest from their origin exhibit inflammatory characters (sanguineous injection, followed by the formation of pus), and blood or pus may frequently be extracted from their cavities unmixed with indurated sebaceous matter. Further, the greasy exudation upon the skin, the follicular elevations with or without inflammation, and the pustules of acne are consequences of different pre-existing morbid conditions of the sebaceous follicles. The accuracy of these remarks in regard to the seat of acne has recently been called in question; but their truth is demonstrated by the minute study of the mode in which the pustules of the disease are formed, and by a comparative examination of the elements composing the skin in different regions of the body.

506. *Causes.*—Billard, in his work on the diseases of infants,<sup>1</sup> informs us that he never saw acne in children at the breast. Children further advanced seem also almost completely exempt from the disease; the great majority of the cases I have met with, indeed, have occurred among individuals from about fourteen to thirty-six years of age. In these, the acne was almost always associated with rosacea, more rarely with sycosis, diseases which, to individuals of maturer years, are analogous to acne attacking earlier in life. As to the causes of acne, they are for the most part extremely obscure. In young females, the disease seems occasionally to coincide with the occurrence of dysmenorrhœa. I have frequently seen it prove ex-

remely troublesome in individuals possessed of the best constitutions; and on the other hand, I have known it attack young persons addicted to certain secret vices, and those subject to abdominal irritations, or given to the use of spirituous liquors. (a)

507. *Diagnosis.*—Acne is a disease easily distinguished from all others. If rosacea, sycosis, and acne are chronic inflammations essentially of the same nature, if they affect the same element of the skin, the three eruptions are still easily distinguished from each other by the regions upon which they commonly make their attacks, and by several other peculiarities which result from the unequal development of the vascular rete, and of the follicles in these different districts of the integuments. Those fiery spots which accompany the tubercles or pustules of one form of rosacea, developed on the nose and cheeks, are never observed on the shoulders or sternal region, however thickly they may be beset with the pustules or tubercles of acne. The pustules and tubercles of sycosis are not seen intermingled with sebaceous concretions and follicular elevations like the pustules of acne. Psudracious pustular syphilis, and some forms of artificial inflammation developed on the skin of the trunk, alone present an apparent analogy with the *dartre pustuleuse disséminée* (Alibert) or acne. Thus psudracious syphilitic pustules, like those of acne, present a small purulent deposit at their apex, and are occasionally scattered over the trunk, but they are not confined to this, and several are seen at the same time on the extremities. Further, the pustules of acne are more prominent than those of the syphilitic affection, which are of a violet hue in the middle, with a copper-coloured base. The skin which separates the pustules of acne is shining, oily, and studded with sebaceous concretions or follicular swellings. In psudracious syphilis, these products of augmented follicular secretion are not observed; the skin between the pustules has its natural colour and appearance. It is occasionally earthy and sallow, indeed, a character which, as being common to many chronic diseases, has been specified very malapropos as characteristic of syphilitic eruptions. The small cicatrices consecutive to psudracious syphilitic pustules differ from those of acne, in being livid and depressed, whilst those of acne are very commonly raised. At first sight, the purple or livid and circumscribed indurations consequent on the pustules of acne might be taken for syphilitic tubercles; but the latter are not preceded by pustules; left to themselves they usually end by becoming ulcerated, and covered by thick incrustations under which there are formed, not white and rounded indurations like those of acne, but small depressed cicatrices, or a kind of irregular zigzags, and spiral puckerings of the skin. Lastly, syphilitic pustules and tubercles are often mixed with spots or papulæ of an unequivocal nature, to say nothing of the other symptoms of lues with which they are always accompanied.

The information received in regard to the diseases which occurred previously to the development of these eruptions, are of less value in establishing the diagnosis than is often believed; from this source presumptions only can accrue, which, hastily adopted as truths, might lead to serious errors. I have treated several individuals successfully for true acne, by means of blood-letting and sulphureous baths, who had been recommended to undergo, or who had undergone a course of mercury, for the sole reason that they had had one or two attacks of venereal disease, and now bore about upon their shoulders certain violet-coloured spots, and sundry small cicatrices.

The pustular inflammations, artificially excited in the skin of the trunk by the application of pitch plasters, with or without the addition of tartrate of antimony, by frictions of croton oil, the juice of the euphorbia, latyrus, &c., differ from acne, not only in the particular causes which excite them, but further, in their progress and external characters. They, in fact, have nothing in common with acne except their seat, which, like that of this disease, is primarily in the follicles of the skin.

508. *Prognosis and treatment.*—When the pustules and follicular swellings of acne are few in number, they are rarely thought of as the

(a) With Copland (*Dict. Pract. Med.*) we would say, that the simple, indurated, and punctated species of acne are most frequently occasioned by uterine irritation and excitement, or an imperfect performance of the uterine functions; by constipation; by torpid conditions of the liver; and by the injurious addiction to onanism.

<sup>1</sup> *Traité des Maladies des Enfants Nouveau-nés et à la mamelle*, 8vo. Paris, 1828.

subject of medical treatment, unless, indeed, they chance to be accompanied with the pustules of rosacea or sycosis. In well-constituted youths and girls they frequently disappear of themselves, seemingly from the changes undergone by the constitution as the period of maturity is attained. The cold bath, frequently repeated, is of great service when the disease is connected with indulgence in pernicious practices, when there are no symptoms present of any chronic affection of the lungs or intestines. When acne can be traced to such causes as those hinted at, and the habitual excitement of the alimentary canal by the use or abuse of vinous or spirituous liquors, it is important, in the first place, to remove and prevent their further operation.

Should a considerable eruption of acne have appeared on the shoulders and bosom in a young and otherwise healthy individual, it will be proper at first to detract some blood, and to make use for a season of acidulated drinks and the cold bath, the effects of which the patient will strive to aid, by leading a regular and quiet life. The cold sulphureous bath may be afterwards employed with great advantage, every day, or every other day, alternately with the simple cold bath, and this is a plan which will generally be found to answer best. I have employed with no less benefit the cold sulphureous douche, especially in that form of the disease which is complicated with follicular concretions and indurations. I have not made many trials of the effects of sulphureous waters administered internally; such as I have made, however, are not favourable to the practice; besides, most patients show a repugnance to so disgusting a drink. Sulphureous waters may, however, be used at the same time internally that they are employed externally by way of bath or douche. The number of sulphureous baths necessary in any case, varies according to the extent and standing of the eruption, and the state of the constitution. When the neck, shoulders, back, and bosom are covered with tubercular indurations, the consequence of long-continued and repeated eruptions of acne, in individuals otherwise well constituted, the vapour bath always assists, and occasionally accomplishes the entire resolution of these indurations.

Lastly, eruptions of acne have been observed appearing each year with the approach of spring, dying away in the autumn and winter, and at length vanishing not to be reproduced, from the sole influence of the progressive development of the organization. (a)

(a) The treatment of acne will be modified by our knowledge of the cause. Thus, where it depends on uterine disease, as dysmenorrhœa and amenorrhœa, we must address our remedies to a removal of these. In some cases of this character, I have prescribed the iodide of potassium, alternated with syrup of sarsaparilla, with the happiest results. I could point to different married women, who had been previously sterile and annoyed at the same time with acne simplex and punctated, and sometimes assuming the appearance of rosacea, become mothers with this treatment, and lose almost entirely their cutaneous disfigurements.

The relief to the system that sometimes follows the eruption of acne will induce caution in the use of repellents for its removal, and at the same time suggest its connection with disordered digestion. The remedies adapted to this latter, will be first used; giving a preference to mercurial and saline purgatives, and antimonials in the first or acute stage—and rhubarb and magnesia, and alkalies and tonics in the second or chronic form. In some cases the mineral acids have been used with good effect.

This treatment and simple regimen are the more necessary where disorder of the digestive organs has been the immediate exciting cause of acne, and where the symptoms of such disorder appear to be materially alleviated by the appearance of the eruption.

Most stress is usually laid on the local treatment of acne, but not seldom in oblivion of correct pathological principles. In its first stage the eruption is the result of irritation and active inflammation; and hence it ought not to be treated either by strong stimulants or repellents. At this time simple vapour, or frequent bathing of the parts with warm water and "gentle friction with the mildest kind of soap," constitutes by far the best local application, before matter has been discharged from the tubercle. "If any vestige of active inflammation remain, it should be soothed, and suppuration promoted by poultices and fo-

### Historical Notices.

509. According to Cassius<sup>1</sup> the word acne is derived from ἀκμή *akmē*, *vigores*, and signifies that the eruption is usually developed about the age of maturity, and is frequently associated with a kind of vigour of constitution. This eruption appears also to have been designated by the names, *vari*,<sup>2</sup> *ionthos*,<sup>3</sup> *puncta mucosa vultus* (Darwin), and *grutum seu milium* (Plenck). It has been described by M. Alibert under the title of *dartre pustuleuse disseminée*.<sup>4</sup> It is a disease of little severity, without important individual varieties, and one of which it seems unnecessary to give the details in particular cases.

### ROSACEA.

Vocab. *Bacchia, Acne rosacea.*

510. Rosacea is a chronic non-contagious inflammation affecting the follicles of the skin of the face, characterized by the successive eruptions of small isolated and acuminate pustules, the bases of which, indurated in different degrees, are surrounded by an inflamed areola. These pustules appear dispersed, especially over the cheeks, nose and forehead, and occasionally extend to the ears and upper parts of the neck. To these pustules succeed a dilated and arborescent state of the superficial blood-vessels in their vicinity, or small, hard, red, circumscribed and excessively indolent tubercular indurations, the resolution of which is always brought about with extreme difficulty, if, indeed, it can ever be accomplished entirely.

511. *Symptoms.*—In its most simple form rosacea appears in the shape of small red pustules disseminated over the face. They are evolved successively without local heat, or any other sensation than that of a very slight tingling in the skin. Each of these pustules arises, suppurates, and dries up or passes into the indurated state independently of those in its vicinity. The suppuration is slow; the tops of the pustules are not covered with a slight scab sooner than the middle of the second week. The pustules of rosacea are frequently seen intermingled with small black points which project more or less from the surface, and are formed by a thick solid unctuous matter accumulated within the follicles of the skin. When these

mentations; and if any tubercle should be found assuming the blue colour without signs of matter coming forward, it should be freely punctured." After the evacuation of the tubercle and the temporary irritation from puncture is removed, Plumbe, whose advice I have just repeated, thinks that stimulants are plainly called for, and of these he gives the preference to spirituous lotions, and particularly to a solution of the bichloride of mercury in proof spirits, in the proportion of five grains of the former to eight ounces of the latter. With this the spots are to be lightly sponged. In acne *indurata*, they who have made trial of the remedy, will join Plumbe in his favourable opinion of the topical use of mercurial ointment, and I would add the recommendation of camphor accurately mixed with it. M. Bielt, again, assures us that none of the resolute preparations for acne *indurata* are comparable to the iodide of sulphur, mixed with lard:

R. Sulphur, ioidid. gr. xii ad xxiv;

Adipis 3i;

M. ft. unguent.

The good effect of all these means is much promoted by the vapour bath, directed in the form of a douche, on the eruption.

A severe but efficient remedy is blistering the diseased surface, a practice first suggested by Ambrose Paré and revived by Darwin.—A solution of the muriate of ammonia is used with advantage in chronic cases of simple acne.

Internally acne *indurata* may be treated by the use of iodide of potassium and iodide of iron together with vegetable syrups, as that of sarsaparilla.

<sup>4</sup> Alibert. *Précis théor. et prat. des malad. de la peau*, t. i. p. 275.

small points are numerous and closely set together, the skin of the nose assumes a thick and greasy appearance, and that of the cheeks becomes rough and uneven.

Commonly, however, the pustules of rosacea are of larger dimensions than those now described; they are then also more numerous and more closely crowded together; their form is conoidal, their base broad and hard, their colour of a ruddy violet; they are indolent, and the pus does not appear at their apices till after the lapse of several weeks. They are occasionally assembled into clusters, and so closely set together that they seem to form a flattened tumour. These pustules are most highly inflamed among individuals of a sanguine temperament and in the prime of life. They are excited by the slightest irregularity in diet, entering a hot room, &c., and under these various influences, they run their course more rapidly; but they then usually succeed each other more rapidly and in greater numbers. In this form of the disease, the follicles and vascular rete of the corion are principally affected, and the subjacent cellular tissue occasionally shares in the swelling of the common integument. After their disappearance the majority of these pustules leave a livid mark behind them, and a depression in the part of the skin they have occupied, which is seldom, if ever, completely effaced.

Another variety of rosacea belongs to the period of perfect manhood. Some red spots, which have appeared on the nose and cheeks, become affected with a troublesome pruritus after meals, a few glasses of strong wine, or a little of any spirituous liquor. By degrees these red patches of the nose become habitual, spread, assume a more vivid hue, and before long look as if studded, here and there, with small pimples, which gradually increase in number, and spring up crop after crop, their yellow purulent heads contrasting strongly with the ruddy violet of the surrounding skin upon which they are evolved. This colour does not vary perceptibly to any great extent, although it looks rather deeper towards evening, after meals, and in the immediate vicinity of the pustules. The parts upon which pustules have sprung up repeatedly are swollen, hardened, and acquire the character of true tubercular *indurations*. The minute veins dilate and form blue lines which ramify irregularly through the substance and over the surface of the skin. The disease spreads upon the cheeks, forehead and chin, and finally gains possession of the whole face; the features enlarge, and the countenance is altered and disagreeable. When the disease has existed for a great length of time, the skin becomes uneven and rugous, and, whatever may be done, can never again be restored to its original and natural state.

Besides these differences in the size, number, and course of the *pustules*, *erythematous blotches* and *tubercular indurations* of rosacea, the disease appears with considerable shades of variety according to the extent of integument it implicates, the length of time it has existed, and the nature of the affections with which it is complicated. In one case the pustules, limited to a small space, are few in number, isolated, and after a time leave no trace of their existence on the skin beyond a slight degree of redness; in another they are very numerous, succeed each other rapidly, sprout over every part of the face, and even spread to the neck. When the disease acquires a great degree of intensity it is frequently followed by dark-red or violet-coloured tubercles of various dimensions; the conjunctivæ inflame; the gums become painful and swell, and the teeth suffer from a chronic form of inflammation which attacks the membrane of the mouth.

In other cases of rarer occurrence than either of these, rosacea does not extend beyond the *alæ* of the nose, upon which tuberculated *excrescences* or *tumours*, of a red colour, and considerable size, are developed. The whole of the tegumentary tissues of the nose are hypertrophied in these cases, so that this member of the face occasionally becomes of twice, and even three times, its usual size.

512. *Causes*.—Rosacea most usually attacks men between the thirtieth and fortieth year of their age; it is very frequently connected with some degree of chronic inflammation of the mucous membrane of the stomach and intestines; its association with a disordered state of the liver is more rarely demonstrated, notwithstanding the opinion to the contrary so incessantly revived. Females seem even more subject to rosacea than men, and are generally attacked about the critical period of life. The disease may also

appear upon any accidental suppression of the menstrual flux, disappear with the return of this natural discharge, or coincide with simple dysmenorrhœa. Rosacea is rarely aggravated by pregnancy; and it occasionally improves or even vanishes entirely during the period of utero-gestation. Rosacea is often of hereditary origin, and may in many cases be traced through several successive generations.

Indulgence in the luxuries of the table, violent or concentrated moral affections, certain professions which require constant application, and an attitude that favours the flow of the blood towards the head, or prevents its ready return from thence, are common causes of rosacea. The use of certain pigments or *rouges* and of cosmetics generally, causes the disease much less frequently than has been imagined.

Cold and moist climates have been supposed to have an influence on the development of rosacea. The disease is certainly more common in England and the north of Germany than in more southern climes; but the circumstance may be explained from the mode of living followed there, the use of a highly stimulating regimen, and the custom of drinking strong wines, and large quantities of malt and spirituous liquors.

513. *Diagnosis*.—Rosacea is easily distinguished from every other pustular disease developed on the face. The pustules of rosacea never attain the size, and are never covered with the adhering scabs proper to those of ecthyma. They do not run together, and never present thick incrustations like those of impetigo; such crusts as they do exhibit are never laminated like those of eczema *impetiginodes*.

The pustules of rosacea are not likely to be confounded with the papulæ of lichen; and the small scabs that form on the tops of its pustules can never be mistaken for the *accidental* thinner and more extensive incrustations, spread over a scaly surface, that distinguish the chronic and excoriated forms of lichen affecting the face. Pustules and tubercles of syphilitic origin are rarely evolved on the face only; they are most commonly observed over the whole of the body, or, at all events, a large extent of its surface at the same time. Syphilitic psudracious and phlyzacious pustules have peculiar and distinguishing characters. When syphilitic tubercles do chance to exist exclusively on the face, they are usually seated around the *alæ* of the nose, about the commissures of the lips, and are almost invariably cleft on the surface, so as to appear like morbid growths. They are, further, distinguishable by their shining aspect, their coppery colour and their tendency to ulcerate. The tubercles by which lupus commences, superficial and very slightly raised at first, will scarcely be confounded with the tubercles that occasionally succeed the pustules of rosacea. The tubercles of lupus increase in size, acquire a livid hue, extend from the nose to the cheeks, and, the subjacent tissues becoming affected, all are alike destroyed by the ulcerative process to which the disease naturally tends; these are circumstances sufficient to render any mistake impossible.

514. *Prognosis and treatment*.—We may hope to succeed in our treatment of rosacea, when the individual affected is still young, when the eruption is recent and of no great severity, and when it can be traced to irregularities in regimen. On the other hand, when the disease has arisen in an individual already arrived at maturity of years; when it has continued long and has every year been getting worse; above all, when it can be traced as a hereditary complaint and is very extensive, whether it be connected with a chronic inflammatory state of the digestive organs or not, the best directed modes of treatment will rarely prove efficient in preventing the evolution of fresh pustules, and will, with great difficulty, accomplish the entire resolution of the tubercles that have already been formed.

The ordinary diet of those who are suffering under rosacea should consist of white meats, fresh vegetables and ripe and watery fruits. They should guard against exposure to much fatigue of body, any degree of nervous excitement, long-continued mental exertion of every kind, and they should carefully shun situations in which the temperature of the air is high.

Should the disease have appeared in a young and plethoric individual; should the pustules be numerous, thickly set and confluent; should the tubercles be inflamed and united by their bases, general blood-letting, repeated at due intervals, the reiterated application of

leeches behind the ears, to the temples and ala nasi are generally beneficial. Ambrose Paré<sup>1</sup> recommends the bleedings practised in cases of rosacea to be copious in order to be efficacious: "The patient," says he, "who is attacked with gutta-rosea must be bled from the basilic vein, then from that of the forehead and next from that of the nose; leeches must also be applied to several spots of the face, and cupping-glasses with scarification put between the shoulders." Should rosacea appear to be connected with the disappearance or any irregularity of the menstrual or hemorrhoidal flux, the return of these evacuations must be solicited by the use of the hip-bath, and the application of leeches to the vulva or anus, at intervals corresponding with the periods of the habitual discharges. Diluents internally, the use of whey, a cooling system of regimen, demi-lavements, the general tepid bath administered at a very moderate temperature or almost cold, fomentations with decoction of bran, warm milk, almond emulsion, veal broth, and decoction of quince-seeds, often aid this plan of treatment in its favourable tendencies.

I must add, however, that all these measures rarely prove adequate to effect the cure of rosacea, and that we are frequently compelled to call in the assistance of certain stimulating remedies in addition. The ancients were in the constant habit of using liniments, into which turpentine, vinegar, soap, myrrh and such articles entered in large proportions. At the present day, from the period of the first attack of the lighter and even of some of the severer forms of rosacea, it is customary, after having abstracted blood to a greater or smaller amount, to employ lotions of rose, lavender or sage water, to which from a sixth to a third of alcohol is added according to the state of the pustules. This practice is frequently followed by very good effects. A solution of from four to eight grains of the bi-chloride of mercury to a pound of rose-water and an ounce of eau de Cologne is also occasionally employed under the same circumstances with the best results.

The sulphureous mineral waters of Barèges, of Aix in Savoy, of Cauterets, Schisnach, Harrowgate, Bath, &c., employed by way of fomentations, baths, and douches, are one of the most powerful means we possess in the treatment of rosacea of long standing. Baths of artificial sulphureous waters prolonged for several hours, are scarcely inferior in efficacy.

The nitrate of silver, and the hydrochloric acid have also been employed to give a character of greater acuteness to the chronic eruption of rosacea. For my own part, I have abandoned the use of both these agents in the treatment of this disease. These, and such applications ought in every case to be preceded by the detraction of blood, and made in such wise as not to penetrate the skin too deeply, a precaution without which they are apt to be followed by erysipelas, ulceration and indelible cicatrices. The nitrate of silver is usually selected to cauterize the pustules when they are isolated, the muriatic acid is preferred when they are confluent.

After blood-letting has been duly practised, the steam douche may be advantageously employed to favour the resolution of the tubercles of rosacea. Directed for twelve or fifteen minutes at a time to the face, this application causes a rapid afflux of blood thither, after which the skin becomes softer and feels smoother than it did before.

Pediluvia, with the addition of a small quantity of the nitro-muriatic acid, and the use of calomel internally, have been recommended in this disease, and I have known the practice occasionally to prove beneficial.

The discussion of the tubercles may be farther solicited by the inunction of ointments, of which the ammoniacal proto-chloride, or the proto-sulphate of mercury forms the basis, in the proportion of about a scruple of either of these salts to an ounce of lard. The iodide of sulphur is also occasionally successfully employed under the same circumstances, in the proportion of from ten to twenty grains, to the ounce of lard.

To conclude this enumeration of remedial means, Guy de Chauliac, Ambrose Paré, and Dr. Darwin, have all at different epochs recommended a blister to the whole, or to a portion of the surface affected with inveterate rosacea. This measure is extremely uncertain in its efficacy, and few patients will probably be found willing to submit to the infliction.

In every case it is right to prolong the treatment some time after the

disappearance of the eruption. It is then that the cold sulphureous douche and aspersion act with peculiar efficacy.

515. So long as rosacea was regarded as a depurative or purifying disease, so long was it the invariable practice to employ purgatives, the juices of the water-cress, scurvy-grass, bccabunga, wild pansy, &c., in its treatment. Remedies of this class are less generally made use of in the practice of the present day, if we except mild purgatives, which I am myself in the habit of prescribing with success, especially to individuals of a nervous temperament and habitually constipated in their bowels.

Should rosacea appear to be complicated with any internal inflammatory affection, such as a chronic gastritis or hepatitis, these diseases require to be combated by measures adapted to their seat, their extent and their peculiar nature. (a)

516. Rosacea declines and fades under the influence of diseases of some severity; its cure has occasionally been succeeded by the development of certain diseases which have then been attributed to its repercussion.

Occasionally treated with temporary success by purgatives or mineral waters, rosacea almost always returns after medicines are abandoned, with a rapidity and regularity that induce despair. (b)

#### Historical Notices and particular Cases.

517. Fernelius<sup>1</sup> has given a good definition of rosacea. Guy de Chauliac<sup>2</sup> has recommended the treatment of the disease by means of a cooling system of diet, bleeding from the frontal vein, the application of leeches within the nostrils, and purgatives. "If these means do not succeed," says he, "we must then blister with cantharides." It is consequently a mistake to attribute this piece of practice to Paré.

Darwin<sup>3</sup> has described three varieties of rosacea, established according to their presumed causes (*Gutta-rosea hepatica*; *Gutta-rosea stomachica*; *Gutta-rosea hereditaria*). Sennertus<sup>4</sup> quotes a remarkable instance of *hypertrophy of the nose* and of *tuberculation (vari)* consecutive to rosacea.

Numerous observations have been published in recommendation of blood-letting,<sup>5</sup> of the application of leeches to the nostrils,<sup>6</sup> of antimonial medicines, the application of blisters between the shoulders,<sup>7</sup> and of the preparations of sulphur.<sup>8</sup>

Several cases have also been detailed of *gastro-intestinal inflammations*,<sup>9</sup> of *amaurosis*,<sup>10</sup> and of different other diseases attributed to the recession of rosacea.

518. I limit myself to the details of two cases of rosacea, in which the methods of treatment most usually recommended were pursued. I also re-publish one of Ambrose Paré's cases, in which the bold

(a) The blue pill, with extract of hyoscyamus, extract of taraxacum, sulphuro-saline waters, and iodide of potassium are useful remedies in rosacea, but they must be aided by a well-regulated and prolonged hygienic course. Liquor potassæ, in a dose of 15 to 30 drops, three times a day in milk or decoction of sarsaparilla, is often very serviceable in this and other skin diseases of the pustular and vesicular forms. Solution of the sulphate of iron is a good application, in rosacea as well as in syccosis: the same may be said of the sulphate of zinc, in the form of tepid solution, by means of rags moistened and applied to the part.

(b) The acne syphilitica of other writers is described by M. Rayer in a subsequent part of this volume, § 871, under the head of "syphilita" by the term *psyrdraceous pustules*.

<sup>1</sup> Rubor faciei vel simplex et solitarius, et vel sine pustulis, vel pustules comites habet. Hæ pustulæ si intensum ruborem habeant, gutta rosacea vocantur, si duræ et exiguæ ex frigido et crasso humore ac velut in callum concretæ, vari nominantur (Fernel. Universa medicina, fol. 1679, p. 442).

practice adopted was crowned with the most complete success. I beg to say, however, that the remedy employed by this celebrated surgeon has been too much vaunted, and, as I have said, few patients will be found ready to hazard its adoption.

CASE LXXV.—*Slight and recent rosacea, hypertrophy of the left ventricle of the heart; treatment by means of blood-letting and mercurialized spirituous lotions.*—Mam'le \* \* \*, nineteen years of age, has been subjected to violent palpitation of the heart for the last five or six years, which recurs as often as she takes active exercise, or is exposed to any moral affection. The pulse is regular, but hard and full. The impulse of the heart is strong. Respiration is unembarrassed; the other functions, and particularly the menstrual flux, are regular.

Nevertheless Mam'le \* \* \* complains occasionally of heaviness of head; and within four months of the date at which my assistance was required, a slight rosaceous affection had appeared. The eruption consisted of but a small number of isolated rosy pustules accompanied with very little inflammation. The disease was not hereditary, and seemed constantly to improve after the recurrence of the menstrual periods, and after the application of the leeches which had been attached to the feet or the præcordial region with a view to calm or to prevent an attack of palpitation. Several follicles, situated upon the *alæ nasi* and neighbouring parts of the cheeks, are distended with solid sebaceous concretions about a line in length. I prescribed fifteen leeches to the feet, and a wash to be applied three times a day to the face, consisting of two parts of rose-water and one of alcohol. This lotion appearing scarcely to stimulate the pustules in any degree, I ordered nine grains of the bi-chloride of mercury to be added to eight ounces of the mixture, a few days afterwards. At the end of a fortnight, the whole of the old pustules were gone and no new ones had been formed. The wash was continued for a fortnight longer. From this period a few pustules of rosacea had been from time to time developed on the face, but the progress of the disease has always been arrested by the application of leeches, a measure which the affection of the heart rendered repeatedly necessary, and by the pains which the patient always took to attack and modify the course of the nascent eruption by the use of the wash I had prescribed for her.

CASE LXXVI.—*Rosacea successfully treated by blood-letting, and the hydro-sulphureous douche.*—Madame \* \* \*, thirty-four years of age, had never suffered from any chronic affection of the skin, when, after long-continued and violent grief, she was attacked at the end of the month of January, 1825, with a number of small red spots which appeared upon the nose and neighbouring parts of the cheeks, and before long became surmounted by small pointed pustules, the apices of which were filled with a whitish or yellow-coloured purulent fluid. This eruption left to itself made rather rapid progress. By the 12th of April the pustules were thickly set, and had spread over the nose and regions of the cheek-bones, the integuments of which were, besides, erythematous and flushed. At this period the patient was seized with a gastro-intestinal inflammation which, in spite of the most active treatment, continued for eight and twenty days. During the continuance of this disease, and under the influence of the depletory measures that were enforced, the rosacea got almost completely well. The eruption reappeared, however, gradually, shortly after the convalescence of the patient, and within two months, had regained the same degree of severity it possessed before the occurrence of the gastro-intestinal affection. Propitious circumstances had again restored to Madame \* \* \* means of leading a quiet and agreeable life; the general health of the patient was good; the chances seemed peculiarly favourable for the treatment of the rosacea, and measures were accordingly taken on the 6th of July, 1825.

The patient was bled from the foot to the extent of twelve ounces; the bowels, habitually constipated, were regularly moved by the daily use of emollient glysters; the patient drank two glasses of whey every day, bathed the affected parts night and morning with cow's milk, and every second day took a warm bath at 25° of Reaumur. Naturally inclined to the most temperate and regular system of life, the patient was anxious to make it still more rigorous, and took particular pains to avoid whatever might by possibility interfere with the success of the treatment.

Its good effects were at first very marked: within two weeks the

erythematous spots which formerly overspread the cheeks had faded; the pustules had shrunk or dried up, and the pruritus, of which the affected parts were the seat, was completely subdued.

The same plan of treatment was continued for two months without other interruption than such as the recurrence of the menstrual periods rendered necessary, and without any other modification than the application of sixteen leeches to the temples. During this interval of time, the efflorescence of the cheeks and *alæ nasi* revived oftener than once without assignable cause; fresh pustules were also evolved; but they were few in number, and speedily dried off. A fortnight later the integuments of the nose were still affected with some degree of redness, and slight desquamation. Madame \* \* \* now took fifteen hydro-sulphureous douches, the steam being directed upon the parts affected by means of a properly constructed spout, with the greatest benefit. From this time, indeed, the rosacea might be regarded as completely cured. When the patient has any sensations of itching in the *alæ nasi* similar to those that preceded the development of the rosaceous pustules in the first instance, by bathing the parts with the mercurial and spirituous wash recommended in the preceding case, (LXXV.) this symptom is appeased, and the formation of fresh pustules prevented.

CASE LXXVII.—*Rosacea treated and cured by the application of a blister to the face.*<sup>1</sup> A certain gentlewoman came to Paris, her whole face deformed with fiery pustules to such a degree that she was shunned by many as affected with leprosy, and being even interdicted from entering her parish church, lest she should infect the healthy. Calling Jacques Hollier and R. Gruaume, physicians, and Est. de la Riviere and Germ. Cheval, surgeons, to take her case into their consideration, it was determined that she was by no means affected with leprosy; and to cure her of her *couperose*, a blister of cantharides was ordered to be applied to the whole of the face. This I accordingly did. And three or four hours after the blister began to tell, she had an extraordinary sense of scalding in the bladder, with gripings, &c., so that she vomited, and made water, and went to stool incessantly, tossing herself hither and thither as if she had been in a fire, and out of her mind from the delirium of a fever, all of which surprised me very much. Seeing that these accidents arose from the cantharides, it was resolved, in consultation, to give the patient abundance of milk to drink, and that injections should be thrown up as well to the neck of the womb as to the neck of the bladder. She was also bathed in water of moderate heat, in which linseed had been boiled, together with the roots and leaves of mallows, henbane, lettuce, &c. In this bath she remained long, finding her sufferings lessened by it. Being then laid in bed again, her loins and genitals were anointed with unguentum rosatum and oxycerate. By these different measures the accidents were all subdued. As to the face, it was completely blistered, and discharged large quantities of purulent sanies, by which it lost the great deformity of skin it presented before. After being cured, we gave the patient a certificate to the effect that she was in no wise leprous. And soon after, having returned home, she got married, and has since had several beautiful children; nor could any one now perceive, for she is still alive, that she had ever had her face flayed.

## SYCOSIS.

Vocab. *Mentagra*, *Whelk*.

519. Sycosis is characterized by the successive evolution of a number of small pointed pustules, similar to those of rosacea, and scattered singly or clustered together, over the chin, upper-lip, sub-maxillary region and lateral parts of the face. This eruption is pretty generally known under the objectionable title of *mentagra*.

520. *Symptoms.*—Slight, partial, and passing pustular eruptions are usually observed to take place for several months, or even some years, upon the regions indicated, before a complete attack of sycosis occurs. In some rare cases, and almost always under the influence of appreciable causes, such as excesses in spirituous potations, the disease unexpectedly attacks the whole of the inferior maxillary region.

<sup>1</sup> Amb. Paré Œuvres. liv. 21. Des Venins, fol. Lyon, 1641, p. 500.

The eruption is occasionally confined to the upper-lip, at other times to one of the sides of the chin, to the lateral parts of the face, or to a part only of the sub-maxillary region; the disease in other instances attacks the whole of the regions indicated above, simultaneously or successively, and even extends to the roots of the hair in the nape of the neck (*sycosis capillitii*).

The evolution of the pustules of sycosis is usually attended with a feeling of heat and tension in the parts they are to occupy. At one time they are disseminated and appear under the form of very small red points which become more and more prominent by degrees. On the second or third day of their formation the tops of these elevations grow white, and are filled with a pale yellowish pus; they subsequently increase a little, but it is seldom that they surpass a millet-seed in size. Almost all of them seem traversed by a hair; they do not discharge like those of impetigo. Between the fifth and seventh day each pustule bursts spontaneously, its sides shrink, and a slight oozing takes place which gives rise to a brownish crust that scarcely adheres to the skin, and is confounded at its edges with the epidemic furfuræ which are thrown off by the inflamed integuments in the vicinity of the pustule. (a)

521. When the pustules are grouped or clustered in considerable numbers, the inflammation extends to the cellular membrane immediately under the inflamed portion of corion, and gives rise to a true phlegmonous swelling. The chin, the sub-maxillary regions and the upper lip then present small hard, painful red tumours covered with pustules, or incrustations of considerable thickness, and a mixed yellow and greenish-brown hue, which might very readily be mistaken for those of impetigo, without attention to the thickening of the integuments and swelling of the subcutaneous cellular tissue.

In the greater number of cases, sycosis, like rosacea, invades in the shape of repeated partial eruptions which succeed each other at intervals more or less remote. When the pustules are thrown out repeatedly on the same places, the inflammation extending from the corion to the subcutaneous cellular membrane, there occasions indurations, which before long present the appearance of voluminous tubercles. These are especially observed among the aged, and in subjects of a flabby constitution in whom the pustular inflammation has not been followed by a perfect resolution. When the eruptions have been copious and severe, and have succeeded each other rapidly, these tubercles increase in number, and spread over the whole extent of the chin. The new pustules which still continue to be evolved on the surface of these tubercles, or in the intervals between them, proclaim the original nature of the disease. It is then particularly that the confused mixture of pustules, tubercles, and incrustations, give a disgusting character to the appearance of sycosis. Arrived at this stage, sycosis is always an obstinate disease, the cure of which is never obtained but with great difficulty.

The skin occasionally becomes very much altered, and swells to such a pitch as to appear covered with moist and vegetating tumours. The piliferous bulbs of the beard frequently participate in the inflammation; and if the disease continue long enough, patches of the integument of the chin, &c., are divested of beard entirely. This loss of the beard is usually only temporary; at a subsequent period, new hairs, of a light colour and very weak at first, make their appearance, but gradually acquire the shade and strength of those that have fallen. The loss of portions of the beard in other instances is permanent.

Sycosis may be confined to the upper lip. Several pustules agglomerated upon this part give rise to a thick blackish scab, which often projects remarkably from the surface of the parts it covers.

When the disease gets well, whether by a natural process, which very rarely happens, or under the influence of remedial measures, no new pustules are evolved, the incrustations are detached, and the tubercles decline in size and hardness. Some slight desquamation

(a) "What has been termed sycosis, is nothing more or less than acne, or follicular obstruction and its consequences, occurring in parts covered by hair; and though the necessity of distinction between it and the same state of parts not so covered be admitted, this circumstance cannot justify a subdivision like that adopted of *S. menti* and *S. capillitii*," Plumbé. The reference here is to the division of sycosis into two species by Willan and Bateman.

occasionally takes place from the points formerly affected, which long continue red and livid, especially in individuals of broken-down constitutions.

The shortest period that sycosis is known to continue is from one to two months; it frequently remains for years, and in spite of the most rational methods of treatment that can be adopted. It is further very apt to recur even after it has been cured, particularly in those individuals who commit errors in diet.

522. *Causes*.—I do not imagine that sycosis is contagious: yet M. Foville assures us that he has seen several of the insane patients in the Hospital of Rouen, successively attacked with the disease from having been shaved with the same razor. Under certain circumstances consequently it would appear that sycosis may acquire the contagious character. Pliny tells us that mentagra spread in Italy by contagion during the reign of Claudius. Was this the same disease as sycosis? The disease makes its attacks more especially among youthful and adult male subjects of a sanguine or bilious temperament, who have a strong thick beard; it is, however, occasionally observed among the aged; it then occurs more particularly among those who have been habitually exposed to strong heats, such as cooks, founders, refiners, &c. Indulgence in the luxuries of the table, the abuse of spirituous liquors and highly-seasoned food, want of due regard to cleanliness, irritating applications to the skin of the face, the use of a foul or rough-edged razor, seem all to favour the development of the disease. It appears more frequently in the spring and autumn than at other seasons. It is rare among females. (a)

523. *Diagnosis*.—It is of some importance to distinguish sycosis

(a) In some instances an analogous affection to sycosis is met with in the pubes of both sexes.

A variety of the disease, termed by M. Gruby *mentagrophyte*, is described as follows by Mr. Wilson (*op. cit.* pp. 301-2).

"*Sycosis contagiosum*.—M. Gruby, of Vienna, who has recently distinguished himself by his researches into the vegetable nature of favus, and by the announcement of the discovery of vegetable formations in other diseases, has just (September, 1842) addressed a paper to the Academy of France, on a new cryptogamic plant, existing in the roots of the hairs of the beard, and around that portion which is contained within the hair-follicle. By the transmission of the seeds of this plant the disease is rendered contagious, and he proposes for it the name of *mentagrophyte*.

"M. Gruby gives the following account of the disease:—It is limited to the hairy part of the face, but is most frequently seen upon the chin, the upper lip, and the cheeks. It covers all these parts with white, grayish, and yellowish scales, which measure from two to six millimetres in breadth, and from three to eight in length. The scales are slightly raised in the middle, their borders are angular, and they are pierced at all points by hairs; they are but loosely connected with the skin, but so closely with the hairs, that in removing a scale we at the same time pull out a hair.

"Examination with the microscope discovers to us that the scales are composed of epidermic cells, but the whole of the dermic portion of the hair is surrounded by cryptogamic formations, which constitute a vegetable sheath around it, in such manner, that the hair implanted in this vegetable sheath may be likened to the finger surrounded by a glove.

"It is worthy of remark, that these cryptogamia never rise above the surface of the epidermis; they originate in the matrix of the hair, and in the cells of which the follicle is composed, and they ascend so as to surround all that portion of the hair included within the dermis. They present everywhere a prodigious number of sporules, which are adherent on the one side with the internal surface of the follicle, and on the other, with the cylinder of the hair; to the former they are very closely connected.

"Each plant is composed of a stem, of several branches, and of sporules.

"This disease of the skin, continues M. Gruby, is an affection of a purely vegetable nature, and is deserving of occupying a place among those disorders—such as favus and aphtha—which consist in the development of parasitic plants, and which might, very properly, be termed *nosophyta*."

from other inflammatory affections appearing on the chin, cheeks and lips, especially from ecthyma, impetigo *figurata*, pustular and tubercular syphilitic eruptions, and boils.

The pustules of ecthyma are larger and more highly inflamed than those of sycosis. The scabs succeeding ecthyma are also broader, thicker, and more adherent, and this disease never gives rise to tubercular indurations.

The small pustules of impetigo *figurata* scarcely rise above the level of the skin, and are not pointed like those of sycosis; they also differ from the latter in the greater rapidity of their evolution, and the more acute symptoms attending their progress. As regards the disposition of the pustules in *groups*, both of these eruptions may present this arrangement. Nevertheless, in sycosis the pustules are most commonly isolated and distinct, whilst in impetigo *figurata* they are generally clustered and crowded together. The pustules of the impetigo burst from the third to the fourth day, and the sero-purulent fluid that escapes from them is quickly changed into yellow continuous incrustations, the thickness of which increases in the course of a few days. The pustules of sycosis again do not give way before the fifth, sixth, or seventh day, and the scabs that succeed them are thin, slight, and isolated. All these distinguishing features, however, are obscured when the pustular eruption of sycosis is considerable and accompanied with a pale yellowish-green secretion from the follicles, or when the course of the disease is very acute, and the pustules are confluent, or much crowded together.

It is rare that the pustules of syphilis appear nowhere except on the lower part of the face; they almost uniformly occur on the *alæ* of the nose, on the forehead, and at the angles of the mouth. The pustules of sycosis, on the contrary, are often limited to the chin, and, indeed generally, to its inferior parts; they are pointed, and arise on a bright red base, proclamatatory of one of the more acute forms of inflammation. Syphilitic pustules are flatter, spring from a coppery, dirty, and almost flabby ground; they are not preceded either by the smarting or painful tensive feeling which announces the pustules of sycosis. In the tubercular state, sycosis might more readily be confounded with the same condition of the integuments proceeding from a syphilitic cause. Nevertheless, the tubercles of sycosis are conoidal in their form; their base penetrates more deeply than the corion, extending even to the subcutaneous cellular substance; whilst those of syphilis are more rounded in their shapes, have a shining look, and appear to arise from the more superficial layers of the corion; they are, farther, primary formations, and not consecutive to pustules like those of sycosis. Moreover, the pustular and tubercular inflammations of the skin induced by syphilis, accompanied as they are, in the vast majority of cases, by chronic phlegmasiæ of the throat and conjunctiva, and almost invariably preceded by severe nocturnal pains, present a group of symptoms that differ extremely from those that characterize sycosis.

In furuncle the inflammation extends from the cellular tissue to the skin; a sloughy core is expelled from an opening which always leaves a scar. In sycosis, on the contrary, the inflammation first attacks the follicles; and the pustules only discharge a very small quantity of pus, by an opening which does not destructively implicate the skin, and which is speedily effaced.

524. *Prognosis*.—The most experienced practitioner frequently finds it impossible for him to fix limits to the probable continuance of sycosis. At the very moment when the decrease in the number of the pustules, and in the violet hue of the skin, seems to promise a speedy recovery, fresh eruptions break forth without any assignable cause, and blight the expectations of the patient and his attendant. In other cases, again, when every appearance leads to the presumption that the disease will continue for years, it is found to yield readily to active measures combined with an appropriate system of regimen. Those cases of the disease generally prove most rebellious which in the chronic state preserve the pustular and primitive form of the inflammation. When this happens, the disease is justly to be regarded as one of the most intractable to which the integuments are subject.

Sycosis occasionally disappears in summer, commonly to return again in winter.

525. *Treatment*.—The first measure in the treatment of sycosis is to

clip the beard with curved scissors, the action of the razor being found constantly to aggravate the disease.

If the disease be of recent date, and have attacked a strong and healthy man, if the pustules be numerous, and crowded in such a way as to indicate a great degree of acuteness in the inflammation, it will be proper to have recourse to blood-letting, general as well as local, and to repeat the operation at frequent intervals, being only careful to apply the leeches, used topically, to a portion of the integuments beyond the limits of the eruption. If the disease continues unchanged, or if it revives after having once declined, the general abstraction of blood ought to be repeated, the operation being occasionally preceded by fresh applications of leeches around the chin. The measure in which blood is abstracted both locally and generally, is in every case to be regulated by the state of the constitution, the intensity of the inflammation, the extent and frequency of the pustular eruptions, and by the effects—beneficial or noxious, which the depletion exerts upon the general health.

General baths and local emollient fomentations are to be employed at the same time, and a mild aperient is to be exhibited at intervals.

When the disease has existed long, and repeated pustular eruptions have given place to a tuberculated and indurated state of the integuments, the local abstraction of blood will still be found useful; under such circumstances, however, the measure is to be resorted to at more distant intervals, and only in the robust and plethoric. It would be hurtful in individuals advanced in life, and of weakly constitution and lax fibre.

When the tubercles of sycosis show no signs of resolution under the influence of emollient topical applications, continued during several weeks, we should then cause the parts affected to be well rubbed with some discutient salve of which the proto-nitrate, the deutoxide, or the protochloride of mercury forms the base. Ointments of the preparations of sulphur, of iodine and of the alkalies, are also frequently employed with the same views. I have occasionally obtained the rapid resolution of the tubercles of sycosis by the inunction of the ointment of the hydriodate of potash and sulphur. It is always proper to suspend the use of this class of remedies for a season, upon the first appearance of a fresh crop of pustules.

The vapour douche is also frequently employed with success in softening the tubercles of sycosis and promoting their resolution. Douches from a watering spout, of the sulphureous waters of Barèges, Cauterets, Aix in Savoy, Bath, Harrowgate, &c., are often found serviceable under the same circumstances.

Among topical applications, in fine, and when the disease is of very old standing and has proved very rebellious, much good is occasionally effected by the employment of superficial escharotics. The concentrated mineral acids, or solutions of the caustic potash have generally been the agents selected. (a)

*Laxatives* are often employed successfully in the treatment of chronic sycosis occurring among the young and robust. *Bitters* and *chalybeate* medicines are found to answer better with individuals in the decline of life, and of a lax and flabby constitution.

The *muriate of gold*, administered by way of inunction upon the gums and tongue, has repeatedly either accomplished or expedited the cure of very refractory cases of sycosis.

Lastly, excellent effects are occasionally obtained from the preparations of *mercury*, as well among those who have never, as among those

(a) On this division of the treatment Plumbe remarks: "The attention to the part should be constant and unremitting, and should consist of warm fomentations frequently repeated during the day, with poultices, if they can be conveniently applied, at night. Every little tubercle should be punctured at its commencement, and every hair extracted from the part which may be got out without much pain. This practice, strictly followed, is capable of removing the most protracted and troublesome cases, without the use of any internal medicines beyond alterative aperients, and any dependence on internal remedies, unassisted by it, will inevitably lead to disappointment."—p. 67.

He recommends as a comfortable and clean substitute for the razor, the razor-scissors, as they are called by cutlers who manufacture them.

who have previously suffered from venereal affections. It frequently happens that we are compelled to try the effects one after another of the whole circle of remedies that have now been mentioned, the disease, as has been said, commonly proving one of extreme obstinacy. (a)

#### *Historical Notices and particular Cases.*

Celsus,<sup>1</sup> Ætius,<sup>2</sup> and Paul of Ægina,<sup>3</sup> have described two varieties of sycosis, one of which evidently agrees with the eruption which has just engaged our attention. Pliny<sup>4</sup> has drawn a striking and accurate picture of the disease under the title of *mentagra*, which he believed contagious. The term sycosis (from *συκωρ*, a fig), only signifies one, namely, the tubercular state of the disease; the word *mentagra*, however, is even more objectionable, inasmuch as it is applicable to any or the whole of the eruptions which affect the chin, and could not be used to designate sycosis affecting the upper lip alone.

Willan, Bateman, and their followers, have done wrong in classing sycosis among the *tubercles*.

I have not been able to meet with the dissertation of Johrenius,<sup>5</sup> who has written expressly on this disease. Alibert has described the affection under the title of *dartre pustuleuse mentagra*. Several cases of sycosis have been particularly detailed in different periodical publications.<sup>6</sup>

CASE LXXVIII.—*Sycosis successfully treated by blood-letting, emollient fumigations and an ointment of the nitrate of mercury.*—A carrier, 38 years of age, of a vigorous constitution, and leading a laborious life, although passionately addicted to spirituous liquors, was attacked with sycosis in the beginning of May, 1825. I was consulted towards the end of July of the same year, and found the eruption to consist, 1st, of a great number of small sharp-pointed pustules, the size of a millet-seed, with hard and inflamed bases, disseminated over the chin, the inferior maxillary region, and the lateral and superior parts of the cheeks; 2d, of some ten red, hard, and inflamed tubercles; 3d, of epidermic laminæ and yellowish crusts, confusedly intermingled with the pustules and tubercles, and adherent to a strong black beard. These parts had long been the seat of painful, tensile sensations and violent pruritus. The symptoms had at one time abated; but, in consequence of several successive eruptions of pustules, the disease had lately gone great lengths, and the whole integuments of the chin seemed swollen. Several lymphatic glands situated under the mastoid processes were enlarged; the principal functions of the body were performed with perfect regularity.

I began by bleeding the patient to the extent of several ounces, and ordered cataplasms of crumb of bread, softened with the decoction of mallows and poppy-heads, to be applied to the parts of the skin affected. The patient took a pint of whey daily, with a drachm of soluble cream of tartar dissolved in it. A speedy improvement was the consequence of this practice. Twelve days afterwards, I had twenty leeches applied to the fore part of the neck, at some short distance from the limits of the eruption. The soothing cataplasms were continued, and emollient and anodyne fumigations were four times administered.

On the twentieth day of this treatment, the skin freed from incrustations and squamæ, no longer showed any pustules; but it was erythematous in some places, and very little change was found to have taken place in the forms and dimensions of the tubercles. I now desired the poultices to be discontinued, and soothing fumigations, and lotions with warm milk to be used in their stead. The beard was removed with curved scissors. On the forty-fourth day of the treatment, the tubercles appeared softer; but the skin was still furfuraceous in places where the tubercles had been evolved. The

patient was purged with Seidlitz water, and the tubercles were gently anointed with an ointment of the nitrate of mercury, the strength of the unguent being gradually increased by an additional dose of the salt. The cure of the disease, in this instance, was accomplished after two months and a half of treatment.

CASE LXXIX.—*Pustular and tubercular sycosis, application of emollients and of the ammoniacal proto-chloruret of mercury.*—N \* \* \* \*, corpulent, and of a lymphatic constitution, was attacked, in the course of 1815, with slight rosacea, which yielded to sulphureous washes. In the month of March, 1824, several pustules, similar to those which formerly appeared on the cheeks, were observed on the chin, and got well in the course of ten weeks, under the use of the same kind of lotions. A second eruption of small pointed pustules took place in the month of September following, not only on the chin, but on the inferior maxillary region likewise, which became covered with thin and slightly adherent incrustations; fresh pustules made their appearance in the intervals between these, and the sulphureous washes, usually employed by the patient with the best effects, seemed now to aggravate the mischief: the skin became more tense, more highly inflamed, and more thickly beset with pustules than ever.

Consulted on the 14th of October, 1825, for the first time, I found but few pustules unbroken; the greater number were covered with dry scabs, retained by being entangled among the hairs of the beard. Several tubercles were disseminated amidst these incrustations, the level of which they exceeded. The skin was of a red colour under the scabs, especially in the neighbourhood of the tubercles. The patient made little complaint of heat or itchiness; and the affection of the skin seemed perfectly free from all complication. The scabs were soon detached and the tubercles softened by the application of emollient poultices. Small doses of calomel were at the same time prescribed internally. Eight days afterwards the only evident change in the state of the parts was their freedom from incrustations. The limits which the redness of the skin and the tubercles extended could now be more clearly perceived. The emollient topical applications, and the calomel internally, in doses of three grains daily, were nevertheless continued; but without any other effect, at the end of three weeks, than a decrease, in a very trifling degree, of the redness of those places which had been beset with pustules. The skin was soft and not painful; the chin was now repeatedly exposed, for several successive days, to the vapour of an emollient decoction; no fresh pustules were evolved. During the space of a month, N \* \* \* \* continued to rub the tubercles gently with an ointment of the ammoniacal proto-chloruret of mercury, the use of this salve being suspended whenever it appeared to be producing too great a degree of excitement. By this means the resolution of several of the small tumours was successfully accomplished. Some others, however, remain indolent, and the skin which surrounded them long continued furfuraceous, although it did gradually resume its natural appearance. Six weeks after the treatment now specified was entered on, with the exception of only four or five tubercles, the resolution of which could not be brought about, the integuments of the chin had returned to the condition they possessed before the invasion of the disease.

CASE LXXX.—*Pustular sycosis in clusters; tubercles; cure accomplished by means of bathing, bleeding, purgatives, and sulphureous and vapour-baths.*—Thomas, aged fifty-one, entered La Charité on the 10th of June, 1833, on account of sycosis. The patient is a sturdy vine-dresser, in the habitual enjoyment of good health. He lives well, and every day indulges in a small glass of brandy, never drinking unmixed wine save on Sundays and festivals.

The sycosis was of but a few days' standing, having been preceded by a considerable degree of itchiness, followed by sensations of pricking over the chin and region of the lower jaw. These parts, twenty-four hours after the attack, were puffed, and beset with numbers of small tumours surmounted by pustules.

June 11th.—On the lower maxillary region, numerous small, hard and prominent lumps of a deep red colour are observed. These implicate the whole thickness of the integuments, and even extend to the subjacent cellular tissue, which participates, over a very considerable space, in the inflammation of the skin. The tumours, which vary from the size of a pea to that of a large filbert, cause no sensation of itchiness, but one of tensile, pricking and pulsatory pain.

(a) *Special diseases of the sebaceous follicles* are treated of by M. Rayer at § 1183 et seq.

Several of the tubercles are covered with dry, gray or yellowish-coloured, and, in some instances, cracked incrustations, which are entangled among the hairs of the beard. The general health is unimpaired, and Thomas makes no complaint besides the sycosis, except of an occasional slight headache. The patient was bled, took the temperate bath, and was put upon the use of whey. June 13th.—There was less uneasiness in the parts of the skin affected; and the headache had left him. (*Softening poultices to the chin.*) 14th—20th June.—Matters much in the same state, although the patient had been purged with castor oil, and a few of the tubercles were lightly touched with the nitrate of silver; several fresh tubercles, indeed, having appeared about the latter date, the patient was bled a second time, and the purgative repeated. These measures were followed by a diminution in the prickling and tension of the affected parts; and when the superficial eschars, produced by the caustic, were detached, the tubercles beneath them were found evidently shrunk, and showed no disposition again to become covered with crusts. In the same measure, however, as these older tubercles declined, others of more recent formation appeared in their vicinity, being constantly preceded by tumefaction of the subcutaneous cellular substance: wherever they were about to be evolved a red spot was apparent on the skin; and at the time of these getting covered with pustules, the subcutaneous cellular substance became hard and swollen.

A calomel and jalap purge was exhibited on the 23d and 26th, and on the 25th the patient was bled a third time. On the 28th he felt himself better; but fresh tubercles still continued to make their appearance.

On the first days of July a discharge of a yellow colour took place over the chin; not, however, from the tubercles themselves, but from the spaces between them, which, by concreting, formed incrustations of the same hue. These scabs were rounded and conical, of no great size, somewhat transparent, and very like pieces of amber in their general appearance. This discharge, of a strikingly impetiginous character, did not continue longer than a few days, and never occurred again.

From the 1st to the 13th of July, the warm bath, whey and aluminous lotions were continued, but without any good effect. On the 17th the inflammation had lost so much of its acute character, that the sulphureous was substituted for the simple bath. During the month of July the patient was farther let blood, three several times, and took active purgative medicine as often. From the 2d to the 9th of August, when the patient left the hospital, the vapour bath was tried every day, in the hope of hastening the progress of several stationary tubercles. The skin had now resumed its natural appearance in many places; no fresh eruption of pustules had taken place for some time; but the thickened portions of the subcutaneous genal and submaxillary cellular tissue were not yet completely resolved. The patient was seen, several weeks after his exit from the hospital, perfectly recovered, having taken no farther steps towards remedying his disease, save such as are usually included under the head of diet and regimen.

## IMPETIGO.

Vocab. *Crusted Tetter, Psudraccia.*

527. Impetigo is a cutaneous affection unaccompanied by fever, characterized by the eruption of one or more crops of pustules, disseminated or collected in clusters, the contents of which dry up before long, and assume the form of yellowish rough and prominent incrustations.

528. *Symptoms.*—Impetigo is a disease that may invade every part of the body. It appears under two principal forms: the small pustules that characterize it being in the one disposed in circular or oval groups (impetigo *figurata*, Willan); in the other disseminated over a surface of variable extent (impetigo *sparsa*, Willan).

Each of these forms of the disease is acute or chronic, according as it consists in a single crop or in successive eruptions of pustules. Between these two principal forms of impetigo specified above, there occur a vast number of intermediate varieties, which are not unfre-

quently observed in the same individual when the disease appears on several regions of the body.

529. Impetigo *figurata*, the *dartre crustacée flavescence* of Alibert, most frequently attacks children at the period of dentition, youths of either sex, and women of a lymphatic and sanguineous temperament, with a florid complexion and a fine skin. It very commonly appears in the spring; and I have seen several young persons attacked periodically at this season for three or four years in succession.

It usually occurs without precursory symptoms. When acute, however, it is occasionally preceded by pain of the epigastrium, general uneasiness, a feeling of lassitude, weakness in the limbs, &c.

The disease is observed on the neck, trunk and extremities, but even more frequently on the face, and almost always on the middle of the cheeks; from thence it is apt to spread to the whole of the malar region, and to the commissure of the lips in such a way as to form a circle upon the face.

When impetigo *figurata* is evolved on the face, and it is watched from the period of its invasion, one or more small red and very superficial blotches are first perceived; these gradually become more conspicuous, and are soon affected with a considerable degree of pruritus. By and by these patches rise and become covered with small yellowish pustules, confluent or agglomerated, and but little elevated above the general level of the integuments. These clusters, of various dimensions, generally of a circular shape, and surrounded by a rosy circle, may continue isolated, or become connected by the development of fresh pustules in their circumference, or by the skin acquiring an erysipelatous tint in the spaces between them. The eruption is occasionally accompanied with severe pruritus and a degree of heat and tingling that amounts to smarting.

After the lapse of three or four days, and occasionally sooner, the pustules burst, pour out a yellowish fluid which dries quickly and turns into thick crusts of a bright or greenish yellow colour, semi-transparent, slightly furrowed, very friable, and in appearance very similar to portions of candied honey, or to the concrete gummy exudations poured out by different trees. A considerable discharge continues to go on under the crusts originally formed, the thickness of which is thus gradually very much increased, whilst their dimensions extend greatly beyond the limits of the pustules that first produced them. The skin in the circumference of the incrustations is red, and frequently presents several small and unbroken pustules the contents of which are scarcely consistent. The integuments under these crusts are of a bright red, and occasionally appear denuded of epidermis.

When impetigo *figurata* is evolved in a young and well-constituted individual, or when the disease is slight, its duration is not necessarily protracted beyond an interval of more than three or four weeks: the heat of the skin gradually abates, the morbid secretion lessens by slow degrees, and before long ceases entirely; the incrustations grow constantly drier, and being detached at length, leave one or more red spots or marks which commonly continue visible for more than a month, and are followed or not, according to circumstances, with a sensible desquamation of the cuticle. Small miliary specks, of a dull white colour, are at times observed upon the remaining red spots; these are owing to a number of sebaceous follicles distended with hardened secretions, or of which the walls have become altered and thickened.

530. Impetigo *figurata* is occasionally met with confined to the eyelids, upon which prominent and conical-shaped incrustations are then produced. This variety of the disease is commonly complicated with a particular species of ophthalmia, or with an inflammatory affection of the follicles of the ciliae.

I have seen this form of impetigo prolonged downwards on either side of the under lip in a very regular manner; and I have remarked it forming a streak upon the upper lip so as to appear like a pair of thick moustaches.

Impetigo *figurata* of the face may become chronic under two forms: 1st, the development of the psudracious pustules is at one time successive; fresh groups are thrown out in the neighbourhood of the yellowish crusts produced by the desiccation of the primary pustules or of the secondary crops developed in the circumference of the first pustular or incrustated clusters, the dimensions of which they

increase. In the latter case, the desiccation and cure commence in the centres of the several groups.

2d. Instead of spreading superficially, the inflammation in impetigo may penetrate the whole thickness of the skin, and even affect the subcutaneous cellular tissue. After the detachment of the incrustations, a fresh discharge may give rise to the formation of new scabs of the same kind; and they may thus fall and be reproduced several times in succession, becoming, however, thinner and thinner on each renewal. The surface of the integuments under them is of a vivid red colour; it subsequently becomes furfuraceous, and the inflammation then seems to acquire something of a squamous character.

When chronic impetigo *figurata* thus approaches its decline, if it be treated by an ill-timed recurrence to stimulants, or if the constitution happens to suffer from any cause, the disease may be fastened, as it were, upon the skin for many months, and even for several years. The parts of the skin that have in this way been repeatedly affected with inflammation, become chapped, and occasionally even present superficial excoriations.

531. The pustular groups of impetigo *figurata* of the face, although usually situated on the malar regions, may be observed occurring in other regions: they are occasionally thrown out on the upper lip, immediately below the septum of the nostrils, and upon the *alæ nasi*. In the latter case, the matter of the pustules may dry in such a way as to produce a conical depending scab, compared by Alibert to the stalactitic formations observed in certain caverns (*Dartre crustacée salactiforme*).

In impetigo *figurata* of the limbs, the groups of psyracious pustules, and the scabs that succeed them, usually circular on the forearms and hands, are of a larger size and less regularly round shape on the lower extremities. The pustules in these situations are evolved in the same manner as on the face, and are soon replaced by thick crusts of a greenish or brownish-yellow colour. When the disease has declined into the chronic state, it frequently happens that no untouched pustule is anywhere to be seen; but the partial eruptions that take place from time to time, and the particular shape of the crusts and of the red marks they leave behind them, is sufficient at any time to characterize this variety.

When recovery takes place, the heat and itehiness of the skin diminish; the discharge becomes less in quantity; the crusts, last produced, are of superior thickness, their edges dry completely, and are occasionally marked out by a white epidermic border. Lastly, after the crusts have been detached, and are no longer reproduced, the skin, of a deep red in the first instance, becomes furfuraceous, and by slow degrees regains its natural colour and appearance.

532. Instead of being arranged in circumscribed groups, the pustules and crusts of impetigo may appear irregularly scattered over the limbs, neck, shoulders, face, and external ears. This constitutes the second variety of the disease—the impetigo *sparsa*.

1. Impetigo *sparsa* of the lower limbs is always a disease of long duration. One of the extremities may be attacked singly, or both may be implicated together, or in succession.

The disease is characterized by small yellowish pustules which appear on the instep, ankles, and especially, on the outer part of the leg. The evolution of these pustules is accompanied with insupportable pruritus. They soon burst and pour out a sero-purulent fluid, which is gradually changed into yellow-coloured laminated scabs of less breadth and thickness than those of impetigo *figurata*. In the spaces between them the skin is reddish, and the cuticle looks rough and shining; a considerable discharge takes place from the pustules for some time; but by and by this becomes smaller in quantity, under and in the vicinity of the crusts, which consequently acquire a more consistent and drier appearance. At the very time when they seem about to be thrown off, however, it frequently happens that a fresh eruption of pustules takes place, accompanied with heat and violent pruritus; and secondary pustular eruptions of this description may go on occurring from time to time, at various intervals, until the whole of one, or of both legs, from the knee to the ankle and dorsal aspect of the foot, are implicated. A sero-purulent fluid then flows abundantly from the surface of the skin, and by drying, encases the limbs in crusts. The crusts often acquire a great degree of thickness in the aged, and among individuals of shattered

constitutions. They are then of a deep yellowish-brown colour, and might very properly be compared to the bark of certain trees (impetigo *scabida*, Willan). The legs are moved with pain and difficulty; the incrustations split, the legs frequently become œdematous, and before long are furrowed by fissures, running in various directions, and of different depths. A yellowish, sero-purulent discharge exudes from these cracks, and forms additional incrustations that appear to gird and enclose the leg. If this hardened exudation be removed in part, or completely, by the continued use of emollient fomentations and cataplasms, the denuded corion which is then exposed, speedily furnishes a fresh supply of discharge, which, before long, concretes into a new incrustation.

Arrived at this stage, impetigo *sparsa* of the lower extremities is a very obstinate disease, especially when it attacks the aged, the weakly in constitution, or the infirm and broken down in health. The inflammation occasionally extends to the toes and secreting matrices of the nails. The nails then become altered, and finally loosened from the skin (*onychchia impetiginodes*). An œdematous infiltration of the legs, and ulcers, which commonly appear about the ankle, are common consequences of this affection. The surface of these ulcers is uneven, and discharges a sero-purulent fluid; their edges are irregular, purple, or livid, and frequently crowned with small pustules full of sanguinolent serum, or, otherwise, they are covered with yellowish crusts of varying thicknesses.

When the progress of this inflammation is successfully arrested—the incrustations become dry, and, once detached, are not again reproduced. The skin in some places maintains a bluish, or purple-red tint, and, in others, where it has been attacked with ulceration, it presents reddish or violet-coloured indelible cicatrices.

2. Impetigo *sparsa* of the superior extremities is most frequently found attacking the forearms; it does not differ from the disease situated on the legs save in being less severe, and more rarely complicated with œdema and ulcers when it has advanced into the chronic state.

3. In acute impetigo *sparsa* of the face, the greenish-yellow incrustations dispersed over the cheeks and clinging to the beard in the adult, are not long of being loosened from the skin. If the inflammation extends to the nose, as it frequently does in childhood, the nostrils become plugged up with thick and dry incrustations; the nose swells, and the disease then commonly passes into the chronic state.

4. Impetigo *sparsa* may also attack the neck, ears, and hairy scalp. The tinea *granulata* of Alibert, and the porrigo *favosa* of Willan, signify one and the same variety of impetigo. Impetigo of the hairy scalp is occasionally met with among adults; but the subjects it most usually attacks are children, and then it appears most frequently about the posterior parts of the head, the entire surface of which may be implicated. The disease appears in the shape of minute pustules of a yellowish-white colour, irregularly scattered over the hairy scalp, their centres traversed by a hair, and accompanied with a high degree of inflammation and excessive pruritus. In the course of from two to four days, these pustules pour forth a fluid that frequently agglutinates a number of hairs together, and dries into small brownish, or grayish rough and irregular crusts or masses, which M. Alibert has compared to fragments of roughly pounded mortar. (a) These incrustations, become dry and friable, are detached from the skin, and remain adherent to the hair, which frequently appears filled with them. A very faint, sickly, and unpleasant smell is exhaled from the head, sometimes of so powerful a nature when all attention to cleanliness is neglected, that the whole atmosphere of a room is contaminated with it. Pediculi multiply rapidly, and swarm among the hair, which is rarely lost in this disease, but very frequently matted or agglutinated into masses by the adhesive qualities of the discharge.

Impetigo of the hairy scalp scarcely lasts longer than some months, and it most frequently gets well with proper treatment in the course of a few weeks.

5. Instead of true impetigo, an eruption consisting of the pustules of this disease and of the vesicles of eczema is occasionally observed to take place (*eczema impetiginodes*). This form of the disease, which

(a) And not unfrequently they may be said to resemble a gummy extract.

commonly proves very severe when it attacks the trunk and extremities, frequently appears upon the wrists, spreads over the backs of the hands, the phalanges of the fingers, and even extends to the matrices of the nails; it may also spread in the opposite direction to the forearm, the bend of the arm, and even reach the nucha and face. More than one or two eruptions of pustules and vesicles usually follow each other successively. The vesicles are slower in their progress than the psudracious pustules, and commonly continue transparent for several days after their evolution. Each eruption is attended with much heat and intolerable pruritus; and soon after its appearance, a sero-purulent fluid is discharged in profusion, which speedily concretes and dries into laminated yellowish, or greenish crusts. The skin is red and occasionally chapped. After a longer or shorter interval, the inflammatory symptoms subside; the cuticle is detached in large pieces; the incrustations fall, and the skin is long left in a rough, dry, squamous and rigid state.

I have observed this form of the disease assuming the arrangement into circular clusters presented by impetigo *figurata*. The groups were composed of confluent or very closely crowded vesicles and pustules. When these raised patches were pricked, shortly after their formation, a limpid serous fluid escaped from the vesicles, and an opaque and purulent matter from the pustules. These fluids by drying, formed circular rugous scabs of a greenish-gray colour: the skin which they covered was tuberculated and unequally tumefied. I have, further, seen the oval-shaped clusters of the impetiginous eczemas get well from their centres towards their circumferences, the situations of the patches being at last proclaimed by a very conspicuous crusted and furfuraceous circumscribing ridge. (a)

6. In the last place, impetigo may occur with a very decided inflammatory character. The integument in the circumference of the groups is then of as vivid a red as it presents in erysipelas, (impetigo *erysipelatodes*, Willan,) and this state of things is often accompanied with general febrile symptoms.

533. Various phenomena frequently appear connected with the local symptoms of impetigo: the lymphatic glands in the vicinity of the pustules may become swollen and painful; the pruritus and morbid heat are occasionally so troublesome, that they prevent the approach of sleep, and impede the due performance of different functions of the economy. The disease, in fine, is frequently seen associated with a gastro-intestinal affection; it is much more rarely complicated with any other form of internal lesion.

534. *Causes.* Impetigo is not transmitted by way of infection, and its causes are very obscure. Children at the period of teething, especially those of a lymphatic temperament and scrofulous constitution, are frequently attacked with impetigo of the face and hairy scalp (teigne *granulée* Alib.), or with the eczematous form of the disease, which is then generally entitled *crusta lactea*; this complaint is more especially and frequently observed among the poor, ill-lodged, badly fed, and filthily disposed classes of society.

Young persons of a sanguineous and lymphatic temperament, with a fine and delicate skin, are occasionally attacked with impetigo of the face, when they have been exposed to the bright rays of the sun in the spring and heat of summer.

In young females whose catamenia are irregular, and among women arrived at the critical age, impetigo is apt to show itself either on the face or on the limbs; in these circumstances, it very frequently attacks the upper lip immediately under the septum of the nostrils.

Impetigo seems occasionally to be induced by the presence of some other inflammatory affection of the skin, particularly by repeated attacks of lichen agrius. The disease seems also, occasionally, to coincide with some derangement of the digestive functions; and this is a complication that is met with very frequently in children during the periods of teething. To conclude, the small pustules of impetigo have now and then been observed to follow excesses of every kind, violent muscular exercise, acute and prolonged moral affections, grief, &c.

535. *Diagnosis.*—Impetigo may present itself in the shape or stage of pustules and incrustations; or the disease may be reduced to its

traces—red marks covered with squamæ, or stains of a yellowish-red hue; it may farther be discovered in different places under each of these different degrees or appearances. The minute pustules of impetigo are readily distinguished from the large pustules of ecthyma, and from the artificial pustules produced by the tartrate of antimony and the inoculation of purulent matter. I have already given the elements of the diagnosis between impetigo, and acne and rosacea §§ 507–513. Impetigo of the hairy scalp is not liable to be mistaken for disseminated favus (porrigo *lupinosa*, Willan), nor with that which appears under the form of circular patches (porrigo *scutulata*, Willan). The pustules of impetigo discharge, whilst those of favus, deeply situated within the substance of the skin, are rapidly changed into dry, yellowish-coloured, cup-shaped scabs. The crusts of impetigo are brown, or of a dull gray, like small pieces of dirty plaster, and never present those broad, thick, and continuous incrustations observed in favus confertus (porrigo *scutulata*, Willan). Lastly, impetigo of the hairy scalp is not contagious, and does not implicate the piliferous bulbs, like favus.

It is more difficult to distinguish impetigo of the scalp from eczema *impetiginodes* of the same region. The principal diagnostic features of each of these inhere in the dissimilar aspects of their incrustations.

The pustules of sycosis, often isolated, and always prominent, are larger in size, and not so yellow in colour as those of impetigo when it attacks the chin; the impetiginous eruption, also, is always very much crowded, and secretes abundantly. The scabs of sycosis are drier, and of a deeper colour than the incrustations of impetigo; they are likewise only reproduced after a fresh eruption of pustules. The crusts in impetigo are of a greenish-yellow hue, thick, semi-transparent, and reproduced without any renewal of the eruption. Tubercles and indurations are encountered in sycosis,—alterations that are never seen in impetigo.

When the vesicles of scabies become purulent, or when they are accidentally complicated with pustules, they are always much larger, and more elevated than the small psudracia of impetigo.

The red and scaly spots consecutive to the formation, or to the fall of the crusts of impetigo, may be distinguished from inflammatory affections originally squamous in their nature, such as lepra, psoriasis and pityriasis, by the circumstance of the squamæ in these latter maladies being accompanied by no discharge, and by their having been preceded neither by pustules nor incrustations. Those pigmentary yellowish-coloured spots, so frequently observed after the cure of syphilitic eruptions and confluent psoriasis, are very seldom seen after the invasion of impetigo. The pustules of impetigo can never be mistaken for those of syphilitic origin covered with black, and firmly adherent scabs which conceal ulcers to which indelible cicatrices succeed (vide *Syphilis*). Lastly, impetigo with its pustules, disseminated or collected into clusters, and its thick, rough, and yellowish-coloured incrustations cannot be mistaken for eczema in any of its forms, with its vesicles, its lamellar crusts, or the thicker squamæ of its latter stages.

536. *Prognosis.*—The prognosis in impetigo is generally more favourable than in eczema, lepra, lichen, &c. The disease, with the acute type, wherever situated, commonly gets well in the course of two or three weeks. The duration of the chronic form of impetigo is influenced by the number of eruptions, the state of the constitution generally, and the existence of other particular conditions, such as amenorrhœa, pregnancy, period of life, presence of scrofula, &c. I have seen the disease appear in a woman each time she was pregnant, resist the most energetic remedial measures, and get well spontaneously a short time after the confinement.

Chronic impetigo on the hairy scalp, of the upper lip, and other regions covered with hair, is often a very intractable disease, especially when the patient is advanced in life, when he is of a scrofulous constitution, or when his health has suffered in any way.

537. *Treatment.*—When impetigo appears with a character of acuteness on the face or hairy scalp of a child during the process of dentition, it is generally advisable to restrict remedial measures to simple attention to cleanliness: the eruption occurring under these circumstances is frequently accompanied with a signal improvement in the state of the constitution, which might be prevented from taking place by any thing like active remedial measures. I have seen the

(a) In the note to page 120, the diagnosis of eczema *impetiginodes* is given by Dr. Carswell.

ill-timed medication and cure of these impetigos, then entitled crusted tetter (dartres crustacées), followed by diseases of different degrees of severity; in other cases, the appearance of the pustular eruption has seemed to me to act advantageously on various old-standing diseases of an obstinate character.

On the other hand, the treatment of certain impetigos is to be conducted on the principle of effecting some modification in the constitution. I have had opportunities of satisfying myself on this point, by treating successfully with the preparations of iron, sulphur, and iodine, several impetiginous eruptions befalling individuals labouring under scrofula. In other cases where the impetigo has been preceded by amenorrhœa or dysmenorrhœa, I have derived great advantages from the preparations of iron and other emmenagogues.

When the state of the constitution affords no particular indication of cure, impetigo, on its appearance, and as often as the eruption is attended with a great degree of redness of the skin (impetigo erysipelatodes), or is distinguished by the abundance of its pustules, is to be treated by means of general blood-letting in adults and individuals in the flower of life, and by leeches in children and the weakly in constitution. Should amenorrhœa or dysmenorrhœa complicate the disease, the vena saphena should be opened, or leeches should be applied around the external organs of generation, especially when emmenagogues have been tried in vain. These bleedings will occasionally require to be repeated. They usually prove detrimental to individuals of a scrofulous or weakly habit of body. Whatever the temperament of the patient, the blood abstracted is almost invariably found to be buffy.

The local or general simple tepid bath at a low temperature (86° or 92° F.); and frequent ablutions with cold water, milk, decoction of bran, almond emulsion, decoction of mallows, digitalis, poppy-heads, &c., are used with advantage in this first stage of impetigo. At a later period, aluminous, saturnine, or alkaline washes, and the application of the ointments of the oxide of zinc, and of the acetate of lead, contribute to accelerate the cure, which often takes place without the necessity being felt of having recourse to any other measures.

In acute impetigo of the region of the beard, or hairy scalp, the hair must be removed with sharp scissors, and the diseased surfaces laid bare. This variety, like all the others, requires to be dealt with by means of emollient applications, and occasionally of blood-letting. Depilation, the utility of which is incontestable in favus, is always injurious in acute impetigo of the hairy scalp, or of the skin; neither is this measure ever necessary in the chronic impetigo of these regions. Saline purgatives, such as the acidulous tartrate of potash, and soda, the sulphate of magnesia, the sulphate of soda, &c., in doses of from two drachms to half an ounce daily, are also frequently employed with advantage.

When impetigo has lost its acute character, or when it has become decidedly chronic, the incrustations are best got rid of by means of the steam douche, which seems very often to have the effect of warding off a fresh eruption. It is even found advantageous to recur to the vapour-douche shortly after the formation of the crusts of impetigo in any stage of the disease whenever the skin appears but little inflamed. These douches directed upon the parts affected, before the formation of scabs, that is to say, during the pustular state of the eruption, or when any considerable degree of inflammation still lingers around the incrustations, are almost always injurious. I have frequently substituted, with good effect, the simple bath and ordinary emollient cataplasm, at a very moderate temperature, for the vapour bath and douche generally recommended in these cases.

2. It is seldom that local blood-letting and emollient and sedative applications are very actively employed in cases of chronic impetigo; although the practice, assisted by gentle laxatives, when the state of the digestive organs offers no bar to their exhibition, is one which, in analogous circumstances, has unquestionably been very frequently crowned with success.

When the skin is but slightly inflamed, and not very irritable, the artificial or natural sulphureous baths of Barèges, Llochesche, Cauterets, Bath, Harrowgate, &c., are often resorted to with advantage at a temperature of from 95° to 100° F., and this is not only in the cases of the elderly and weakly, but in those of individuals in the spring and

vigour of life, possessed to all appearances of an excellent constitution. The time of continuing in these baths ought to be gradually prolonged, and ultimately carried to the length of several hours each time (§ 127).

The sea-water and the alkaline bath are generally less beneficial; yet it does sometimes happen that taken every day, or on alternate days, along with the fresh water bath, they act more beneficially than the sulphureous bath. Alkaline washes are usually prescribed at the same time; and these may be combined and alternated with the use of acidulous lotions.

Dr. A. T. Thomson has recommended the medicinal hydrocyanic acid in impetigo. I have tried it in the proportion of two drachms to half a pound of distilled water, as a lotion with some success. I cannot affirm, however, that its action was more salutary than that of the sulphuric or nitric acid largely diluted with water. Should the skin chance to become excoriated, these hydrocyanic acid lotions must be laid aside; and in no case are they to be used but with extreme reserve.

Ioduretted-sulphureous lotions have been particularly recommended by M. Alibert. They appear to be more especially useful in cases of impetigo attacking subjects of a scrofulous constitution.

In chronic and inveterate impetigo, when the eruption extends to but a small surface, the parts affected are frequently cauterized to good purpose with a solution of the nitrate of silver, with the *potassa cum calce* in substance, or the dilute hydrochloric acid.

I have also occasionally used with good effect, under similar circumstances, an ointment consisting of a scruple of the proto-nitrate of mercury to an ounce of hog's-lard.

I have very seldom ventured on the application of a blister to surfaces affected with impetigo, although this measure has been recommended and employed with advantage.

Compression is an auxiliary measure which I have frequently instituted with the happiest results in impetigo *scabida* affecting the lower extremities and complicated with œdema, ulcers, varicose veins, &c.

Charcoal was formerly lauded as a topical application in the treatment of impetigo, and particularly when the scalp was the part affected; I have not made the action of this article a subject of such particular study as to be enabled to speak from personal experience of the degree of good which results from its application.

538. There are other medicinal substances whose action on the evolution and progress of impetigo is incontestable. I have treated very obstinate impetigos successfully by the *nitric acid* in doses of half a drachm daily, in a pint of barley-water sweetened to the taste. When this sherbet seems to distress the stomach, it is generally enough for patients to suspend its use for a few days, and to take a warm bath at convenient intervals, in order to be enabled to resume it. It very seldom happens that this medicine is continued for a month or six weeks without accomplishing a cure.

I have, in fine, seen a small number of very old and inveterate cases of impetigo which have only yielded to *antimonial* and *arsenical* medicines. These remedies are of course to be administered with every precaution for the patient's safety; their use being suspended during an interval of several days, as often as their action on the system appears to be becoming excessive. In this way all notable and permanent injury, as well to the digestive organs in particular as to the system at large, is avoided, without the curative effects of the medicines being in any degree diminished.

Several other compound and simple medicines of various degrees of activity, such as the juice of the apium *graveolans*, the decoction of sarsaparilla, of dulcamara, of the ulmus *pyramidalis*, of the root of the arum *maculatum*, &c., have been used with success in certain forms of chronic impetigo (*crusted tetter*); but the individual cases, in which the use of these substances is preferable to those I have mentioned more particularly, have not yet been very satisfactorily ascertained. (a)

(a) Considering the temperament and constitution of those who are most frequently attacked with impetigo, we cannot refuse to it a scrofulous origin or at least a complication with scrofula;—and, in so regarding it, we shall be led to the employment of the remedies generally thought to be best adapted to that disease. Of course a preference will be given to mild laxatives, the use of the mineral acids, and

*Historical Notices and particular Cases.*

539. If, at the present day, impetigo be an affection but little known to a number of practitioners, we have to thank the confusion that still reigns in the nomenclature of the diseases of the skin; the various senses in which this word has been used (Vocab. impetigo), and the multiplicity of expletives that have been introduced to designate the acute or chronic, the pustular, encrusted, furfuraceous or erythematous state of the disease, the varieties in appearance it assumed as it affected the trunk, hairy scalp or extremities, may be fairly charged with the principal blame as causes of this prevailing ignorance.

The Greeks appear to have referred to this disease under the title of *ψωρα* *ελαωδης*.<sup>1</sup> Celsus<sup>2</sup> has included under the name of *impetigo*, not only the pustular disease we have just been discussing, but two other squamous affections, namely, lepra and psoriasis. Willan<sup>3</sup> was the first who gave an accurate account of impetigo; he fell into a mistake, however, in describing impetigo of the scalp as a particular disease, under the title of *porrigo favosa* (Vocab. porrigo). M. Alibert, who had described impetigo affecting the trunk, under the title of *dartre crustacée*, and impetigo of the scalp, under that of *teigne granulée*, in his "*Precis des Maladies de la Peau*," has more recently designated the first of these forms of the disease, by the name of *méliagre*, and the second by that of *porrigo granulata*.

Impetigo has long been designated in France under the title of *dartre crouteuse*, or *crustacée*, and in England, under that of *humid or running tetter*.

Impetigo of the scalp has been described by Forestus<sup>4</sup> under the head of *favus*, a term which, at the present day, is applied to another disease; it has been particularly, but erroneously noticed, as already stated, by Willan, under the name of *porrigo favosa*, and by Alibert, under that of *teigne granulée*.<sup>5</sup>

The Latin translators of Aëtius<sup>6</sup> signalize impetigo of the face under the denomination of *ulcus melicerida*.

Callisen<sup>7</sup> describes impetiginous eczema under the title of *herpes pustulosus*.

Dr. A. T. Thomson<sup>8</sup> has published some observations on the iodine, and especially the iodide of iron, and, at times, cinchonic preparations.

In the acute stage of impetigo, or where it is accompanied with fever, reliance can only be had on antiphlogistic remedies, both general and topical, as recommended in the text. Dr. Crampton has treated a series of cases of impetigo *capitis*, and other forms of scalp affections, almost entirely by constitutional remedies, of which the principal ones were purgatives and the warm bath.

Mr. Erichsen (*Practical Treatise on Diseases of the Scalp*), coincides with M. Rayer in his high estimate of nitric acid; and he also uses the nitro-muriatic.

In the more obstinate cases which resist the milder treatment, and which, happily, are comparatively few in number, recourse may be had to the bichloride of mercury in the dose of a sixteenth of a grain united to extract of hemlock, or Fowler's solution in minute doses. Donovan's solution, in doses of five to twenty drops, has cured some old cases of impetigo.

Plumbe lays great stress on the local treatment, in the frequent removal of the diseased secretion; the benefit from which, if carried into effect by frequent ablution of the part with warm water, is incalculable. "By this plan, in conjunction with the exhibition of simple alteratives, entirely rejecting any thing in the shape of ointments or other greasy applications, the disease will be often entirely subdued."

In using the hydrocyanic solution, the favourite lotion of Dr. A. T. Thomson and Plumbe, the caution in the text is worthy of all attention and observance.

external use of the prussic or hydrocyanic acid in the treatment of impetigo. Cases of, and remarks on, this disease have been consigned in several periodical publications,<sup>9</sup> and inaugural dissertations.

Marcolini<sup>10</sup> has described lepra, and not impetigo, under the latter title. The observations of Sauvages, and of Peter and Joseph Frank, on impetiginous affections are very obscure, and convey no ideas but of diseases badly defined and imperfectly described.

CASE LXXXI.—*Acute impetigo of several parts of the skin; rapid cure by blood-letting, vapour baths, and purgatives.* A master mason, twenty-seven years of age, of a sanguineous temperament, came to consult me on the 12th of April, 1826, on account of a disease of the skin, under which he had laboured for nearly six weeks. On the left cheek there were two humid crusts, an inch in diameter, of a yellow colour, prominent, and with circumferences slightly inflamed. A crust of the same sort, but of smaller dimensions, was seen on the chin, and on the right cheek, there existed a cluster of small psyracious pustules. A fourth incrustation, the size of a double sovereign piece, was observed on the back of the left hand. And on the fore-arms and insteps, four additional isolated scabs, of a yellowish-brown colour, dry, adherent to the skin, and from an inch to an inch and a half in diameter, were remarked. In other respects this individual enjoyed excellent health. I bled him to the extent of twelve ounces from the arm, and prescribed the sulphurated lemonade for his drink. Eight days afterwards three simple vapour baths were taken. The scabs were detached, and red marks, of the same dimensions, alone indicated the situations they had occupied on the skin. I then prescribed a couple of doses of sulphate of magnesia, half an ounce to each, dissolved in a weak infusion of senna leaves. The use of the tepid bath a few times confirmed the cure, which in this case was accomplished by the twenty-fifth day of the treatment.

CASE LXXXII.—*Impetigo figurata of the leg; occurrence of the same disease five years afterwards on the face, cured by the steam douche; an analogous eruption proving salutary in a child.*—I was asked on the 18th of September, 1831, to see M<sup>lle</sup> \* \* \*, aged twelve years, of a sanguineous lymphatic constitution, who had been troubled for the last twelve days with a slight excoriation of the right leg. On the anterior aspect of the tibia, there was a small inflamed surface an inch and a half in diameter one way, by an inch the other. The skin here was red, moist, denuded in its epidermis, and presented a great number of small pores, similar to those that are observed in impetigo figurata, when the incrustations have been removed a short while after their formation. The inflamed surface was discharging a yellowish, sero-purulent fluid. A number of small yellowish, or white-coloured pustules, which scarcely rose above the level of the skin, were observed in the circumference of this excoriated spot, and under it, a small cluster of psyracious pustules was remarked. The pustules had appeared without any assignable cause.

The health of M<sup>lle</sup> \* \* \* was excellent. The affected parts were occasionally the seat of pruritus, so violent in its character, that the young lady had the greatest difficulty to restrain herself from scratching them, although she knew that such indulgence would certainly be followed by an aggravation of her complaint. I recommended that the parts should be frequently bathed, during the course of the day, with Goulard's wash, and that the excoriations should be dressed with saturnine cerate, and kept covered with a crumb of bread cataplasm softened with decoction of mallows. This simple dressing allayed the itchiness, and lessened the inflammation. No fresh pustules appeared to be forming. M<sup>lle</sup> now took a few sulphureous baths, and made a rapid recovery from her slight attack of impetigo figurata. In the month of April, 1826, after long-continued application to her studies, M<sup>lle</sup> \* \* \* was a second time attacked with impetigo, which on this occasion made its appearance on the face. Several small clusters of yellow and slightly prominent psyracious

pustules were evolved in succession during fifteen days, on the cheeks, chin, upper lips, ears, and *alæ* of the nose, each of which was speedily converted into yellowish crusts, very similar in their colour to the gummy exudations of certain trees. The integuments at the base of these clusters were not inflamed. The disease in this instance yielded in the course of twenty days to the use of the steam douche.

During the same year, a child of three years old, the brother of this young lady, who had long laboured under a chronic inflammation of the mucous membranes of the cæcum and colon, was attacked with a similar impetiginous affection of the skin of the face. The appearance of this eruption having coincided with the entire cessation of the cæco-colitis, I did not take any immediate measures for its cure. After continuing about two months and a half, the impetigo seemed, if the expression may be allowed, to have exhausted itself, and now left no traces of its presence, save a few red blotches upon the face. The child had not for a long time enjoyed such health as it did subsequently to this attack.

CASE LXXXIII.—*Traces of impetigo sparsa on the upper extremities; impetigo figurata on the limbs; tuberculations of the skin covered with crusts; dysmenorrhœa; cure.*—Marie Halé, aged thirty-one, married, and having had two children. Since her last confinement, eight years ago, she has been irregular in her catamenia, and the discharge has been scanty; she now suffers from leucorrhœa, which becomes more abundant on the return of the menstrual period.

Towards the end of the year 1829, she had the first attack of a disease of the skin, similar to that she is now labouring under (impetigo), from which she recovered, after having been under treatment for three months and a half. Two years subsequently (1831), the patient had a second attack of the same complaint, and about a month before her admission into the Hôpital de la Charité, on the 10th of March, 1833, she was seized for the third time, with the same cutaneous affection. An eruption of small pustules made its appearance successively on the outer part of the right and then on that of the left thigh, spreading to the knees of the same side. The pustules were yellow on their summits, and, bursting, discharged a quantity of yellowish fluid, which concentered into greenish-looking scabs. The forearms, the lower third of the arm, and the posterior surface of the right ear, were also, in their turn, affected with the same kind of pustular eruption. The pruritus was not very distressing, and the appetite had not sensibly fallen off. At the period of her entrance into the hospital, several *crusted patches*, rounded, dry, hard, rough and uneven, of a yellow, or yellowish-green colour, and raised about three lines above the level of the skin, were perceived in the situations mentioned. These scabs were, further, thinner in their circumference than towards their centre, and were loose for about a space of two lines around their edges, being simply in contact with the surface of the dermis which looks red and dry in these situations, although, upon the removal of the whole of the incrustation, which is easily affected, it then looks moist and tender, and of a vivid punctuated red colour. Under some of the scabs, a number of small rounded white points are remarked which resemble nothing more closely than those white bodies which are occasionally seen on blistered surfaces. Under others, the corion is uneven, and presents a tuberculated or mammillary appearance. The incrustations are of very various dimensions, from two or three lines to an inch and a half in breadth. They also vary somewhat in their appearance in different places. (*A drachm of subcarbonate of iron.*)

March 11th.—The patient was put upon the use of barley-water with the addition of half a drachm of nitric acid to each pint of fluid. Emollient poultices were ordered to the forearms, and the chalybeate was continued in doses of thirty-six grains. 13th.—The forearms were less scaly (*alum wash*); pricking and unpleasant scalding. The iron and nitric acid were ordered to be continued, the latter in the dose of a drachm daily. The alum-wash was found to irritate the parts to which it was applied too much, and was consequently discontinued, the emollient cataplasms being resumed in its stead; on the 19th the simple warm bath was prescribed.

19th.—The tender skin was anointed with hog's lard, and this measure, together with the daily use of the warm bath, was continued to the 7th of April. At this date the improvement was very conspicuous; the skin was now less fiery, and the crusts and squamæ of

the thighs had not been reproduced. As the menstrual period approached, the baths were discontinued. On the 10th the catamenia not having made their appearance, sixteen leeches were applied to the external parts, which bled freely. On the 11th the patient was found pale and weak. The baths were resumed on the 15th, and on the 21st the nitric acid, of which the patient began to complain, was replaced by the citric acid, and the vapour bath every other day was substituted for the hot-water bath. The iron was continued as before. The patient was getting well rapidly. For the last twelve days no squamæ had been reproduced; the skin in the parts affected assumed a pale rosy hue; it was now soft and pliant, although still in a less degree than in health,—it no longer looked clear and shining; the mammillary tubercles had disappeared from the left thigh. In the course of the month of March, the leucorrhœa was diminished in quantity; the catamenia appeared some days earlier than anticipated, and, proving scanty, a few leeches were applied by way of substitute. On the 10th of May the parts of the skin that had been affected, were almost completely natural in their appearance.

CASE LXXXIV.—*Eczematous impetigo occurring during pregnancy; loss of the hair and nails; cure.* S. Lainée, nineteen years of age, of a sanguineous temperament and robust constitution, presented herself among the out-patients of the Hôpital St. Antoine on the 14th of September, 1828. She gave us to understand that in her childhood she had been affected with a cutaneous affection, precisely similar to that under which she now laboured, and that she had had a second attack in the course of the year 1827, during her first pregnancy. Seven months and a half gone in a second pregnancy, she became for the third time affected with an eruption of small psyrdracious pustules which were scattered over the surface of the trunk, and especially of the abdomen, and surrounded at their bases by a pretty distinct areola. A number of pustules of the same kind appeared here and there collected into groups, and around these the rosy circle was more particularly conspicuous. A number of greenish scabs or incrustations, not quite so thick as those of impetigo generally are, were also remarked in various situations. These adhered strongly to the skin, and were encircled by a violet-red coloured line. Lastly, between these incrustations several spots were remarked of a dirty violet hue, the surface of which was either smooth or covered with slight squamæ; they had, however, been formerly furnished with crusts similar to those of other districts of the skin.

Between the 18th and 21st of September, many groups of pustules appeared on the trunk and extremities, whilst others that existed previously were drying off. On the 25th the eruption had increased to such an extent as to render blood-letting necessary, which was accordingly practised to the amount of twelve ounces. On the 28th the trunk, (the abdomen in particular) was covered with irregular round-shaped scabs, from an inch to an inch and a half in diameter, yellowish in their colour, rather moist and of considerable thickness. The intervals between the scabs were occupied with many small pustules, irregularly scattered, or congregated into groups of six, eight or ten together; the patient could not move in her bed without suffering acute pain, so completely was every part of the body beset with recent pustules or covered with older incrustations; she also endured a great deal from a sense of pricking and of increased heat in the integuments generally; the pulse was hard, the tongue of the same vivid red which is seen in scarlet fever, the thirst very great. On the 22d the face was flushed, the features swollen, the pulse full and frequent, and the pustules still more numerous than yesterday, covering the arms completely, and with the previously existing incrustations producing so much stiffness that it was found impossible to straighten them sufficiently to perform the venesection which was held necessary.

From the 30th of September to the 2d of October, the inflammation of the skin ran very high; portions of the cuticle, from the confluence of the pustules, were raised in different places, so as to resemble purulent bullæ. In the evening of the day last named, (2d of October) the patient was taken in labour, which went on through the 3d, during the afternoon of which day the patient became delirious and alarmingly ill. She was bled to the extent of ten ounces. She was delivered during the night and immediately fell asleep.

On the 4th, the patient still complained of a feeling of general heat

which, however, was less troublesome than it had been. The tongue had now lost the preternatural redness which it had exhibited during the whole course of the disease. The progress of the eruption appeared to have received a check; the lochia flowed naturally.

On the 6th a few fresh pustules made their appearance on the face, and on the seventh several purulent deposits, were observed under the cuticle of the palms of the hands and soles of the feet. The incrustations over the trunk generally were now either removed or in progress of being cast off. The fall of the crusts was succeeded by the detachment of large epidermic laminæ from the surfaces that had been affected.

The patient complained greatly of pain and heat in the lower extremities, the epidermis of which, entirely detached from the cutis vera beneath, by the motion and rubbing of the parts, formed a sort of prominent roll about the middle of the leg. The exposed corion was red and humid. The purulent exudations, which had taken place in the palms and soles, were for the most part confluent, and formed continuous flat vesications in these places. From the 6th to the 12th, the eruption and consequent stages of scabbing, detachment of the crusts, and desquamation of the cuticle, were repeatedly renewed; the epidermis of the soles of the feet was thrown off in a single piece on the day last mentioned. The nail of one of the toes was at this time half loose, and before the end of the first week in December the whole of these appendages were detached in succession.

The loss of the epidermis was followed by that of the hair on the coronal and parietal regions.

On the 15th of December the patient had completely recovered. The nails and hair grew again at a later period. (a)

(a) The following description of disease and cure by Dr. Carswell is instructive.

"The next case is one of impetigo, which occurred in a boy ten years of age, of sanguineous temperament. He had generally enjoyed good health, although he has had two or three times an eruption on the head. The first occurrence of the eruption was two years ago, just after the death of his father, who, he said, had an eruption on the head at the time of his death, and from whom he supposed he caught it, although a brother and sister, equally exposed with himself, had no eruption.

"The present eruption occurred two months ago, a few pustules only occupying a small spot, which discharged a good deal, and gradually spread.

"On his admission there was an eruption on the top of the head, on the left side, consisting chiefly of incrustations, of a dry, rather brittle appearance, of a dirty, yellowish-gray, or brownish colour, intermixed with, and spreading amongst the hair. The elementary character of the eruption was not seen on any part of the head at this time, but it soon after appeared in the form of the acroes pustule; that is to say, a small prominent pustule, larger than the psyraceous, containing a yellow-coloured fluid pus, which, after a short period burst, and spread its contents amongst the hair, which became converted into yellowish-gray or brown crusts. By means of these characters we recognized the presence of impetigo. The prominent pustule, with its fluid contents, were sufficient to establish the diagnosis, and to distinguish the eruption from porrigo favosa and porrigo scutulata, the two contagious forms of pustular eruptions of the scalp. When we can accomplish this important point, we need not trouble ourselves to find out whether an eruption of the scalp is one of porrigo larvalis, or porrigo granulata, as they have improperly been called, as both of these eruptions are modified forms of impetigo, or of eczema impetiginodes, and are not propagated by contagion.

"The general health of this boy was good, and remained so while he was under treatment, except on one occasion, when he had fever for two days, from derangement of the bowels. The treatment continued for about the same length of time as in the preceding case. It was commenced by the removal of the hair, and the application of poultices. The patient was allowed full diet, and the bowels were regulated by small doses of calomel and rhubarb every alternate night. The removal of the hair on the affected parts was accomplished by the daily use of the alkaline ointment, and washing with warm water and soap.

## FAVUS.

Vocab. *Porrigio favosa*, &c.; *Tinea favosa*,

540. The Romans made use of the word *favus* to signify the cell or collection of cells of the waxen comb in which bees store up their honey. From some analogy in point of form, the word has been impressed into the service of medicine and used to delineate a chronic inflammatory affection of the skin, essentially contagious in its nature, and principally characterized by the appearance of its scabs which are of a clear yellow colour, very dry, strongly adherent to the skin, circular and cupped, and either isolated, or agglomerated into continuous masses with raised and inverted edges, the surface of which presents numerous characteristic depressions. (b)

"On several occasions, however, the eruption spread, or appeared on previously healthy parts of the head, and also on the ears, by the formation of pustules, to which the same means of treatment was applied. After this had ceased to occur, and the inflammatory stage had subsided, the zinc ointment was employed for some time; and, lastly, the nitrate of silver, which completely checked the further progress of the disease.

"The affected parts of the head did not present that baldness and glossy appearance of the skin, which were observed in the cases of porrigo favosa. On the contrary, the hair was only thinned and shortened, and the skin presented numerous dark points, indicating the protrusion of others from its surface. In most cases of impetigo, which constitute a great number of the pustular eruptions of the scalp, the treatment employed in this case will prove successful, when the general health is not impaired, and proper attention is paid to food, clothing, and exercise. In debilitated and scrofulous children, however, general treatment requires special attention. Besides attending to the circumstances just mentioned, and regulating the biliary and intestinal secretions, the warm or shower-bath, according to circumstances, must be employed, combined with mild tonics, together with the use of those remedies which act in a special manner on the capillary circulation, and thereby promote the important functions of secretion and absorption. And no remedy in our possession exercises such a speedy and beneficial operation in this respect as the iodide of iron, particularly when aided by the other general means to which I have alluded. In debilitated, scrofulous, and especially anemiated children, its remedial agency is often remarkable. I need not remind you that its use is counter-indicated in all cases of gastro-intestinal irritation, and even where local inflammation of a sthenic character is present. These states must first be subdued by proper antiphlogistic treatment."

(b) The student of dermatology is not a little embarrassed by the different divisions, as well as names of some of the *pustula*, and particularly of the impetiginous and favous, or porriginous forms. The five genera of pustular diseases, according to the arrangement of Bateman, viz: *impetigo*, *porrigo*, *ecthyma*, *variola* and *scabies*, have, as this writer properly remarks, "nothing in common in their character, except the appearance of pustules in some state of their progress; for some are contagious and others not, some are acute, and others chronic." Of the four varieties of pustules; *phlyzium*, *psyracium*, *achor*, and *favus*, the first three are chiefly used as expletives in description, while the latter is, by M. Rayer, employed to characterize a distinct form or species, which corresponds with the *tinea favosa* of his first arrangement, the *teigne faveuse* of Alibert.

"*Phlyzium* is a pustule commonly of a large size, raised on a hard circular base of a vivid red colour, and succeeded by a thick, hard, dark-coloured scab. *Psyracium* is a small pustule, often irregularly circumscribed, producing but a slight elevation of the cuticle, and terminating in a laminated scab. Many of the psyracia usually appear together, and become confluent; and after the discharge of pus, they pour out a thin watery humour, which frequently forms an irregular incrustation.

"*Achor* and *favus*. These two pustules are considered by the majority of writers from the Greeks downwards, as varieties of the same genus, differing chiefly in magnitude. The *achor* may be defined a small acuminate pustule, containing a straw-coloured

541. *Symptoms*.—Favus occurs principally on those regions of the common integument of the body which lie over a dense and strongly reticulated stratum of cellular tissue, abundantly provided with piliferous follicles. It is therefore very commonly seen on the hairy scalp, from whence it sometimes extends to the temples, forehead and eyebrows, more rarely reaching to the shoulders, the lower parts of the scapular regions, the elbows and forearms, situations in all of which, however, it is occasionally met with; I have even seen it extending over the whole of the back part of the trunk as far as the sacrum, and attacking the knees, and upper and inner parts of the legs in a child, twelve years of age, whose hairy scalp escaped completely. The hands and forearms may also be exclusively implicated; but the disease in such cases may almost always be traced to the accidental inoculation of the contagious discharge upon these parts.

The pustules and scabs of favus are in one instance *disseminated*, in another they occur disposed in circular or oblong clusters; according to these different appearances two varieties of the disease have been established: 1, favus *dispersus*; 2, favus *confertus*.

542. Favus *dispersus* (porrigo *lupinosa* Willan). This form of the disease, according to Willan and Bateman, makes its attack under the form of very minute pustules, not very evident to the naked eye, scarcely rising above the level of the skin, and from the very day of their formation covered on their apices with a small yellow scab. These pustules, in fact, contain the merest globule of pus, which is not shed on the surface but concretes and dries in the interior. I have myself seen these small yellow pustules in several cases of favus. Their existence, however, has been disputed by Messrs. Mahon and Baudelocque. The latter allows, nevertheless, that the favous matter is deposited in a fluid state within the hairy bulbs. The difference of opinion, consequently, seems to turn upon a variety of meaning attached to the word *pustule*. Whatever the mode of formation of the pustules, this is certain, that the matter of favus is not long of appearing on the exterior in the shape of crusts, which at the very earliest period of their existence present a small cup-shaped depression in their centre. The dimensions of these crusts increase, still preserving the circular form and depressed centre peculiar to them. They occasionally attain a magnitude of five or six lines in diameter. Some short time after the appearance of the first incrustations, others are commonly evolved in their vicinity or in other regions of the body. When very numerous and coherent, the scabs of favus by their aggregation compose continuous incrustations of considerable extent, on the surface of which the capped form of the individual crusts may frequently be recognized. Should it happen, indeed, that this peculiar shape is lost through the copiousness of the secretion around them, by carefully removing the superficial layers, each particular favus,

matter, which has the appearance, and nearly the consistence of strained honey, and succeeded by a thin brown or yellowish scab. The *favus*, or *χένιον* is larger than the *achor*, flatter, and not acuminated, and contains a more viscid matter; its base, which is often irregular, is slightly inflamed; and it is succeeded by a yellow, semi-transparent, and sometimes cellular scab like a honeycomb; whence it has obtained its name." Bateman's *Practical Synopsis*.

Impetigo is characterized by the appearance of the small pustules denominated *psudrasia*; while porrigo (of Willan and Bateman) is principally distinguished by an eruption of the pustules denominated *favi* and *achors*. Objection has been made, and with good reason, to the abuse of the term *porrigo*, since some of its forms, viz; *P. larvalis*, and *P. favosa*, are now ranked under the *impetigines* and constitute impetigo *figurata* or *capitis* (impetigo *eczematosa*); and *P. furfurans* belongs to one of the varieties of *eczema*, rather than to the *favi*; while *P. decalvans* is more a result of prior disease of the scalp than a disease itself: it is one of the varieties of alopecia. Hence there are but three forms of porrigo left, *favosa*, *lupinosa* and *scutulata*, which, as both M. Rayer and Mr. Wilson judiciously remark, should be merged in the species of favus,—the two varieties of this latter, *F. dispersus* and *F. confertus* corresponding with *P. lupinosa* and *P. scutulata*. These remarks on porrigo, apply with equal force to tinea, and we may join in the expression of the wish of recent judicious and experienced dermatologists, that the former should be, as the latter is become, an obsolete term.

centrally depressed and isolated, may still be very distinctly made out.

The cup-shape, assumed by the crusts of favus, have caused them to be compared, as already stated, to the cells of the honeycomb, to the depressions, observed on the seeds of the lupine (whence the denomination porrigo *lupinosa* of Willan), or to the capsules of certain lichenous plants that grow on trees. When the crusts of favus are recent they are of a yellow or tawny colour. As they grow older and drier they gain a clear yellow or whitish cast, they then crack, shiver, and become reduced to a powder which bears a considerable resemblance to pulverized sulphur. They then present nothing like regularity of form. These crusts are deeply set in the skin, to which they adhere firmly by their edges.

According to M. Baudelocque their primary seat is under the epidermis.

When a crust of favus, of recent formation, is removed with such care as to cause no effusion of blood, it is found to present a round nipple-shaped elevation, surmounted by a contracted, and, as it were, strictured portion, which enlarges until it terminates at the surface of the skin. On a point of this mammillated surface a slender, conical and moist prolongation is occasionally seen. In the corresponding point the skin presents a small, smooth depression, proportioned in size to the crust, from whence a serous yellowish and transparent fluid exudes. If the crust, thus detached during life, be of older date, its deep surface no longer presents any nipple-like projection, and its thickness at its centre and around its edges is very nearly uniform. The outer central depression corresponds with a slight convexity of the inner aspect of the incrustation. Under the older crusts the skin presents a circular depression, wider and generally of less depth than in the *favi* of more recent formation. Freed from a recently formed scab, the skin speedily regains its natural thickness, and the cuticle is reproduced without any remaining cicatrice when no new crust is formed.

The large incrustations of favus, formed by the agglomeration of several contiguous scabs, are not generally observed to possess any particular form or regular disposition of parts. Their deep or inner surface presents several slight projections separated by linear depressions. The skin under these incrustations presents a number of small, superficial, lenticular depressions separated by linear elevations and inequalities corresponding with the depressions observed on the inner aspect of the incrustations. Under the depressed points the skin is occasionally reduced to half a line in thickness; the papillæ are red and denuded, but not ulcerated even in those situations where the crusts appear buried in the skin. On each of these depressions a minute red central point is perceived, which is often traversed by a hair, and a small red circle which corresponds with the margin of each particular scab. To conclude, I have occasionally found the skin softened and of a violet-red colour under very old incrustations in favus. (a)

(a) "The yellow substance which constitutes the crusts of favus has been satisfactorily proved, by recent investigation, to be an organic growth of simple structure, and bearing a marked resemblance to those inferior numbers of the vegetable kingdom, denominated *mould*. The structure of these crusts appears first to have attracted the attention of Remak, who had observed, so early as 1836, their composition of 'fungoid filaments.' Professor Schoenlein, of Zurich, next called them to notice in a paper in Müller's Archiv. for 1839, on the pathology of the impetigines, in which he makes no doubt of the fungous nature of the substance, and he illustrates his communication by a rude figure of the appearance which they presented in his observations. In pursuance of Schoenlein's researches, they were examined by Fuchs and Langenbeck, of Göttingen; more recently they have been studied by Dr. Gruby, of Vienna, who expresses himself to have been ignorant of the labours of Schoenlein. Dr. Gruby has, moreover, given a clear and lucid description of the growth, which he regards as a parasitic plant, and has determined it to belong to the genus *mycodermis*. The following is an abstract of a paper, from the pen of Dr. Gruby, on this subject, in Müller's Archiv. for the present year:—

"The cup-shaped crust of favus is situated upon a depression of the dermis, and is covered by a sheath of epidermis, which is thickest

The smell of the scabs and incrustations of favus is singularly like that of the urine of the cat. When they are softened with emollient cataplasms the smell changes and becomes faint and sickly, and something similar to that of bones which have been boiled with their ligaments. The crusts thus detached are speedily reproduced with the

on its concave, and thinnest on its convex surface. Immediately within the epidermis is a thin layer of amorphous substance, composed of minute molecules; this layer is dense, of a sulphur-yellow colour, and forms a capsule, which is in contact by its external surface with the epidermis, and by its internal surface with a fungous growth. The parasitic growth is attached by means of its roots to the yellow capsule, while its stem and branches extend inwards towards the centre of the capsule, and constitute the whitish-gray and porous contents of the crust. The roots and branches of the mycoderm are smooth, cylindrical, transparent tubuli, which divide dichotomously from point to point. The interior of the tubuli is filled with a granular substance, and divided here and there by transverse septa. At the ends of the branches are situated the seeds of the plant which are of a yellowish-white colour, and either collected into an irregular assemblage, or disposed in the form of a garland. The diameter of the branches of the mycodermis is  $\frac{1}{1000}$  to  $\frac{1}{25}$  of a millimetre; that of the molecules contained within the tubuli,  $\frac{1}{10000}$  to  $\frac{1}{1000}$  mm.; and that of the seeds,  $\frac{3}{100}$  to  $\frac{1}{100}$  mm. Dr. Gruby has detected seeds in the follicles of the hair, and impacted in the ducts of the sebaceous glands.

"To ascertain the degree of contagious power of the mycodermis, Dr. Gruby inoculated various mammiferous animals, birds, reptiles, and insects, but unsuccessfully; he was equally unsuccessful in his own person, but succeeded, after seventy-six attempts, in reproducing the mycodermis in a cryptogamic plant.

"Mr. Busk, in a paper entitled 'Observations on Parasitical growths on Living Animals,' in the Microscopic Journal, (No. 10,) has given an excellent figure of the mycodermis. He represents the crusts as consisting of a series of oblong cells connected by their extremities.

"However closely the fungous growth here described may resemble a plant, its vegetable nature is very far from being established. The simplest forms of animals are composed, like the mycodermis of cells, variously connected together; and subsequent research may prove the growth under consideration to be of a similar nature. To my mind there is nothing improbable in the supposition of the origin of the growth from morbidly developed epidermic cells of the hair-follicle, or from the corpuscles of the sebaceous substance. In a preceding section of this work, I have shown that the latter are susceptible of considerable alteration, and that in this state they assume an appearance widely different from that of their normal condition. Mr. Busk also entertains doubts with regard to the vegetable nature of the mycodermis, and deduces an opinion favourable to his opinion, from the chemical analysis of the crusts of favus, given by Thenard, who found them composed of

Albumen . . . .	70
Gelatine . . . .	17
Phosphate of lime . .	5
Water and loss . . .	8

100

"Dr. Carpenter, in his 'Principles of Physiology,' (p. 453,) speaking on the same subject, remarks—"It has been assumed that the organization is vegetable, because it (mycodermis) consists of a mass of cells capable of extending themselves by the ordinary process of multiplication. But it must be remembered that the vesicular organization is common to animals, as well as to plants, being the only form that manifests itself at an early period of development in either kingdom, and remaining throughout life in those parts which have not undergone a metamorphose for special purposes. Hence, to speak of *porrigo favosa*, or any similar disease, as produced by the growth of a vegetable within the animal body, appears to the author a very arbitrary assumption; the simple fact being, in regard to this and many other structures of a low type, that they present the simplest or most general kind of organization." Wilson (*op. cit.* p. 322-4.)

characters that are proper to them. According to Thenard, they consist of seventy of albumen, seventeen of gelatine, five of phosphate of lime, eight of water and loss in every 100 parts.

The skin occasionally preserves its healthy characters between the crusts of favus; but, when the groups are numerous or much crowded, it frequently presents a morbid redness, and undergoes repeated furfuraceous desquamations.

In the majority of cases, and when the disease is properly treated, the depressions in the skin disappear after the fall of the scabs; the situations occupied by these, however, being still indicated by the presence of small-violet coloured spots, which disappear at length.

The skin may become ulcerated in old cases of favus affecting the scalp (*tinea favosa*). Small sores two or three lines in diameter, occasionally succeed the primary depressions. Under the larger incrustations the skin now and then presents an assemblage of small ulcers, separated from each other by crevices of varying depth.

The alteration and fall of the hair are the usual consequences of favus when it attacks parts provided with this appendage of the skin. The hair reproduced by the bulbs that have been affected is thin, white and woolly. Those parts that have lost their hair long continue smooth and shining. If the disease remains unsubdued for several years, the baldness may become general and permanent. Lastly, the skin has been seen altered or destroyed through its whole thickness, the hair bulbs and subcutaneous cellular substance the seat of small abscesses, and the inflammation extending to the periosteum and bones of the cranium, which have even been found changed in a greater or less degree in their structure.

543. Favus of the *hairy scalp* often causes a chronic inflammation of the glands of the neck and occiput. This effect is by no means constant, however; I have seen individuals who had long laboured under this form of favus without experiencing any such consequence. It is important not to confound these secondary inflammations of the lymphatic glands with those affections of the same parts, which individuals of scrofulous constitution are so apt to suffer from, before and altogether independently of the appearance of favus.

Pediculi are usually found in vast numbers among the crusts of favus; and children seem to enjoy a sort of ecstasy in tearing their scalp with their nails. The blood mixed with the discharge poured out in these and similar cases, by drying, forms incrustations of a colour different from that presented by the ordinary crusts of favus.

When favus appears on other regions of the body, the inflammation usually penetrates less deeply, it terminates much more rarely by ulceration, and its cure is much more readily accomplished.

Favus of the *trunk* and *extremities* is almost never attended with any other inflammatory affection of the skin; and unless it happens to be inoculated by accident it is very seldom seen complicating other cutaneous diseases. I have, however, had a man under my care, with *impetigo sparsa* of the lower limbs, who presented a single, but perfectly characteristic, crust of favus on the outer part of one of his legs.

I have met with favus developed solely on the cheeks and on the chin.

544. Favus *confertus*.—Favus and the cup-shaped crusts which characterize it, are occasionally seen upon the hairy scalp arranged in such a manner as to form circular *clusters* and regular *rings*. This variety of favus has been described by Willan as a particular species of porrigo (*porrigo scutulata*, the pustular ring-worm of several writers and the vulgar, *tinea annularis*, &c.). At the present day it is impossible to consider this eruption otherwise than as a variety of favus.

Favus *confertus* as it affects the scalp, is also frequently seen existing at the same time, and with the same external form, on the forehead and neck. It is characterized by circular, red-coloured patches, on which appear numerous small yellowish points (*pustules*, Willan), buried within the substance of the skin, not prominent, and generally traversed in the centre by a hair. These small yellow points, much more numerous in the circumference than in the centre of the circular patches, are soon succeeded by scabs which unite in such a manner as to form incrustations of a breadth corresponding to the extent of the eruption, and commonly circular in their shape. Dry and friable, these incrustations are detached from time to time in small pieces, which bear a strong resemblance to the crumbling mortar

of a wall that is going to decay from the effects of age and moisture. The hair, the bulbs of which are often affected from the commencement of the disease, speedily becomes thin, looks dry, and falls out on the slightest touch.

If this form of favus be left to itself, not only do the areas of the primary groups extend, but new ones are formed either spontaneously, or in consequence of the successive inoculation of the matter or powder of the original clusters. When these groups become very numerous they often get blended by their corresponding edges, and then appear as extensive and irregular patches. The circular character of the primary clusters, however, is still indicated by the portions of arcs of a circle distinguishable in the circumference of the larger incrustations. The hairs break off short, or are thrown out by the roots; but are soon succeeded by others, which are shed like the first. If the hair follicles are destroyed or seriously altered, the baldness remains permanent.

*Favus confertus* may denude several different parts of the scalp in succession. There is always room to apprehend the development of fresh incrustations, so long as any redness remains and a furfuraceous desquamation goes on in the parts that have been affected. Recovery, on the contrary, is at hand when the skin becomes less and less inflamed after the fall of the incrustations, and is only affected with very slight eruptions, successively at longer and longer intervals from each other.

545. I have observed that the intellectual faculties frequently appeared to be very limited in the individuals affected with favus; others again seemed prematurely stricken with the signs of old age. Favus of the scalp may be accidentally complicated with otitis, ophthalmia and coryza. One of the severest of these complications, however, is that with a chronic inflammation of the mucous membrane of the stomach and bowels. Bayle has remarked the occurrence of a chronic enlargement of the mesenteric glands, and several other lesions, which, however, on a careful review, do not seem to be more frequent in subjects affected with favus than in those labouring under other diseases. In inveterate favus, which has continued beyond the periods of childhood and youth, the nails of the feet and hands are occasionally found to exhibit particular alterations: they increase in thickness, become very much elongated, look rough on their surface and acquire a yellowish colour, analogous in some degree to that presented by the crusts of favus itself.

546. *Alterations of Structure.*—Duncan and Underwood assigned the bulbs of the hair as the seat of favus. According to Sauvages it principally affects the sebaceous follicles; this opinion was adopted by Murray: “*portioem sedem mali in folliculis dietis pinguidinosis, vel ipso textu celluloso quærendam arbitror*,” and has been lately reproduced in the following terms by the Messrs. Mahon. “An inflamed follicle gives out a morbid humour which becomes dry, fills and distends its cavity and at last causes its rupture and destruction. The depression in favus is nothing more than the orifice of the follicle which is now become visible; and the renewal of the disease is brought on by the evolving of a fresh favus on adjoining follicles, which compressed by the dilatation of the part, cannot be filled and distended nor break and be destroyed until after the renewal of this one. The object of the favus is in part, to destroy the bulb of the hair, which when brought about, the diseases disappears.”

The frequency of favus in those situations where the hair is most abundant,—the scalp, especially, and the regular presence of several hairs in each favous scab, induced M. Baudelocque to believe that the disease was evolved in the piliferous bulbs. The matter of favus deposited within the cavities of these follicles, according to him, concretes and forms a nucleus, which he designates under the objectionable title of *tubercle*. The secretion going on, he adds, concretes around the central nucleus, increases its size, and soon fills, and even distends the cavity of the follicle. The favous deposit, seeking a passage to the exterior, now penetrates the neck of the follicle, but being retained by the cuticle at its orifice, there dries into one with the duct. The same process is repeated as each fresh quantity of secretion attempts to escape; so that the solid part, conical at first, becomes broader by degrees, and ends by being changed into a cylindrical body, and then into a slightly convex superficial crust in proportion as the orifice, by being enlarged and, as it were everted,

approaches the level of the bottom of the follicle, the cavity of which is thus finally transformed into a superficial excavation. Lastly, the neck and orifice of the follicle cannot increase without the skin that surrounds them being pressed back upon itself in all directions, undergoing some slight increase in thickness, which is always in proportion to the degree of condensation endured.

The central depression in the crusts of favus is not the effect of accident. According to the author just quoted it depends on the conjunction of the following circumstances:—1st. The presence of a central cylindrical nucleus, confined by the cuticle, with which it is connected exteriorly in such a way as not to be capable of being elevated; 2d, the forcible detention of the favous secretion in the space around the central nucleus, the sides of the follicle and the epidermis; lastly, a gradual elevation of the detached epidermis, and consequent increase of height in the interval within which the favous fluid is confined.

The progress of the disease causes all trace of the whole of these conditions to be lost. When the cavity of a follicle, by the dilatation of its neck and orifices, is converted into a slightly concave superficies, if the secretion still goes on, the fluid by accumulating under the scab pushes it outwards, and forces back the corion towards the subcutaneous cellular membrane and circumjacent parts. The cuticle then gives way around the whole circumference of the incrustation, which is thrown off unless it happens to be retained by the hairs which pass through it; the follicle then resumes its original form; the cuticle is renewed, and the cure might be spontaneously accomplished did no new favous pustule make its appearance to continue the disease. When the rupture of the cuticle is only partial, the favous incrustation continues adherent to the skin; the secreted fluid oozes out, spreads and dries in the circumference of the primary scab, the diameter of which it thus increases, but, no longer encountering any cause of limitation, being no longer moulded in any peculiar manner, it forms prominences and depressions, which contrast strongly with the regularity of the central and primary scabs. It is by these inequalities that the point at which the epidermis has ceased to regulate the desiccation of the discharge may be ascertained.

547. In this explanation, M. Baudelocque, in common with many anatomists, has assumed that the epidermis, instead of penetrating into the interior of the piliferous follicular depression as far as the bulb, is reflected upon the hair near to the external orifice of the follicle. Mr. Chevalier, and several other anatomists, in whose opinions I myself concur, believe that the epidermis descends into the cavity of the follicle as far as the bulb of the hair, before being reflected along it. The following hypothesis, consequently, appears to me more tenable, and more in harmony with the disposition of the parts. I agree with M. Baudelocque that the orifice of the follicle is plugged by the favous matter drying and adhering strongly on the one hand to the neck of the hair, and on the other to the epidermis, which is reflected at the entrance of the follicle. The secretion of fluid going on continually from the inner surface of the follicle, which becomes gradually more and more distended, it may be supposed that the thin and but slightly extensible epidermis which is reflected into the follicle, gives way under that part where it is intimately connected with the kind of stopper formed by the concrete favous matter; farther, that this matter penetrates between the dermis and cuticle which is detached, and that it forms, by drying, a circular incrustation, prominent in its circumference and depressed in its centre around the central nucleus.

Be this as it may, it is, nevertheless, easy to distinguish the following particulars after death, in well-marked favus of the hairy scalp. On the inner aspect of the skin, a certain degree of redness corresponding to the clusters of the disease, and a certain number of small yellowish-white coloured deposits of a solid substance, perfectly identical with that composing the external incrustations. The minute swellings penetrate the substance of the true skin, and cellular membrane by an elongated tapering extremity. A hair is very frequently seen issuing from these favous deposits.

548. The presence of a hair in these collections, their seat, their form and their size are so many particular circumstances inducing me to believe that the favous matter is deposited in the dilated cavities of the cuticular conduits of the hairs; at the same time, the very slender and finely tapering form of the deep extremities of the deposits leads

me to suppose that the greatest quantity of the matter, thus concealed within the substance of the skin or in the cellular membrane beneath it, is not contained in the proper cavity of the piliferous follicles.

The degree in which the structure of the skin is changed in favus varies extremely, according to the standing and condition of the disease. In the more recent cases the conduits of the follicles are simply dilated by the accumulation of the favous fluid. In some cases we might be tempted at first sight to regard the skin as destroyed through its entire substance, were we not aware that the return of the integuments to their natural condition, and the cure of the complaint, advanced to the same state, without a trace of cicatrice, demonstrated the fact of there having been no important change undergone, far less any actual loss of substance experienced.

After inveterate favus of the scalp, the skin of the cranium, in unhealthy children, may ulcerate and become resolved in parts into a kind of fibrous reticulation surrounding numerous perforations of the corion, at the bottoms of which the pericranium is occasionally seen inflamed, and even the bones of the skull exposed and in a state of caries. (a)

549. *Causes.*—Next to eczema and impetigo, favus is the most common of the chronic inflammations that affect the hairy scalp; it is not observed in the same proportion on other regions of the body. Favus attacks both sexes indiscriminately and may make its appearance from infancy till a very advanced period of life. By far the greatest number of invasions, however, occur in the seventh, eighth or ninth year, but especially in the seventh. In the elderly and bald-headed in whom the piliferous follicles are atrophied or have disappeared, favus is almost never developed on the scalp. The soles of the feet and palms of the hands also enjoy immunity from this disease.

Favus is a contagious disease, and is readily communicated among children who make use of the same comb or brush, especially if any slight excoriation happen to exist on the scalp. In the first edition of this work I quoted a remarkable instance of the inoculation of favus. Here is a second of the same kind. A woman living in the Rue de Bucherie, was in the daily habit of carrying about one of her children who laboured under favus. She was by and by attacked on the forearm that supported the head of the child, with a small cluster of favus, the yellow, dry, and cupped incrustations of which were perfectly characteristic. This woman and her child had been sent to me by Messrs. Olivier (d'Angers) and Bricheteau, who had satisfied themselves, before I saw the cases, that no pustules or crusts of favus existed on any part of the body. The disease in this instance, evidently contracted by contagion, was removed by rubbing the parts affected with the nitrate of silver. The Messrs. Mahon have also published several remarkable cases of favus transmitted by contagion. Several others may be found in the *Journal Hebdomadaire*, tom. iv, p. 72. This disease is held sufficient cause of exemption from military service in France.

I have farther to add, that the same law which obtains in the case of many other diseases, transmissible by contact or inoculation, holds

(a) Mr. Erichsen (*op. cit.*) believes favus to be a modification of tubercle.

“Favus, in its elementary form, differs from pustule,—1st, in the favous matter being poured out upon a free surface, and not upon or within the cutis, and under the cuticle:—2d, the favous tubercle is frequently chronic, existing in an imperfectly developed state for a length of time, which is never the case with pustule. Favous matter differs from pus,—1st, in concreting very quickly after it is poured out, even before exposure to the air:—2d, in its chemical composition; favous matter containing much more earthy salts, and coagulated albumen, than pus. Favus and tubercle agree in their seat [the lining membrane of the hair-follicles appearing to Mr. E. to partake, in a great measure, of the characters of mucous tissue], in the manner of their formation (both being eliminated in a fluid state, but solidifying very quickly,) in their mode of growth (by eccentric deposition, and not by any increase from within), in form, colour, and chemical composition; in most of the causes that predispose to, or excite them; in the age at which they most frequently occur; and in the colour of the cicatrices which are left.” (p. 117.)

good in regard to the contagion of favus. The application of the crusts of favus to the skin is not invariably followed by the inoculation of this disgusting disease.<sup>1</sup>

Favus *confertus*, or pustular ring-worm (*porrigo scutulata*, Willan,) commonly attacks children from the age of two years to the time of puberty. Willan had seen one child in a school communicate the disease to fifty others in the course of a month. In this instance he condemns, with great reason, the filthy practice, so often pursued in establishments for the education of youth, of using the same comb for the whole of the children. I once attended a little boy, five years old, affected with this eruption whose mother contracted a number of pustules on her fingers from washing his head twice a day with an emollient decoction. The two sisters of this child, with whom he was constantly in contact, were attacked with similar pustules on the upper lip, and on the fingers.

Neglect of proper cleanliness, and the presence of some other inflammatory affection of the hairy scalp appear to predispose to both varieties of favus; the disease may also arise spontaneously, and independently of contagion. According to the Messrs. Mahon, annular favus is a more frequent disease in the south than in the north of France. The complaint is very common in England.

550. *Diagnosis.*—Eczema, impetigo, and pityriasis of the hairy scalp, have at different times been assimilated with favus, and described under the same generic name of *tinea*. To have escaped this error, it would have been enough to have reflected that the former diseases do not alter their nature from being evolved on the scalp, and that favus occasionally appears exclusively on the trunk. Had there been even a total want of general features distinguishing it from these diseases, the contagious nature of favus ought to have prevented pathologists from associating it with such affections as eczema and impetigo. Of all the diseases of the skin, however, favus is the one the external characters of which are without dispute, the least equivocal. No other affection is characterized by the evolution of minute pustules which do not rise above the level of the skin, and no other is proclaimed on the exterior by dry, circular, cup-shaped incrustations.

In the hope of obtaining exemption from military duty, attempts have frequently been made by the young men in France to simulate favus, by producing with the nitric acid yellow stains or eschars on the hairy scalp; but these spots want the characteristic depression in their centre, and no one familiar with the appearance of the actual disease could possibly be duped by such artifice. The small pustules of favus *confertus* (*porrigo scutulata*) buried in the skin and covered with incrustations almost from the moment of their formation, cannot be confounded with the pustules of impetigo, the secretion of which does not form true crusts till after the lapse of several days, and then the majority of them are rounded and much less adherent to the skin than those of favus. Farther, impetigo is not contagious, and rarely causes the loss of the hair, whilst favus on the contrary is propagated by the powder of its incrustations, and frequently occasions baldness. The red patches of herpes *circinnatus* at the commencement, and those of lepra divested of their squamæ might be mistaken, if cursorily examined, for the red spots which precede the appearance of the crusts of favus *confertus*; but these crusts by their formation speedily dissipate all doubt on the subject.

551. *Prognosis and Treatment.*—Favus may get well spontaneously after a continuance of several months, or terminate naturally by the fall of the hairs of the affected follicles. Most frequently, however, the disease, abandoned to itself, continues unmitigated for several years. It is in general so much the less under the control of treatment, as it implicates a larger extent of the surface of the scalp, and as it is complicated with other more serious diseases.

When favus is evolved spontaneously towards the decline of an acute or chronic affection of some severity, or when it has attacked feeble and weakly children whose health has improved since its appearance,—in these rare cases all treatment must be indefinitely suspended. By this advice I would not be esteemed as giving in to the opinion of an English writer who has classed favus among those cutaneous diseases which exert a salutary influence on the constitution; I am satisfied, on the contrary, that favus almost always interferes with

<sup>1</sup> Gallot. *Recherches sur la teigne*, p. 64, et suivantes (premier, deuxième et quatrième faits), 8vo. Paris, an. xi.

the due development of the physical powers and the moral and intellectual faculties of those children who have been long and severely affected with it. If some cases of serious disease supervening on the cure of favus have been quoted, an infinitely greater number of instances of improved health and of greater vigour of constitution have been recorded after recovery from this disgusting disease. To secure these happy consequences, the regimen and plan of life pursued by patients require particular attention, especially when the disease appears among individuals of scrofulous constitution and who are suspected to have tubercles in their lungs.

552. If favus has appeared exclusively on the trunk, or on the extremities, in consequence of direct exposure to infection, and the scalp continues exempt, the disease in the majority of instances, will be found to yield to the use of plain, alkaline or sulphureous bathing. If the whole of the disease consists in a few scattered incrustations, after having succeeded in removing these, the parts affected must be touched with the nitrate of silver. The black crusts or eschars produced by the action of the caustic, become depressed or cup-shaped, like those of favus, and after their fall, leave a more superficial circular red mark, which is itself effaced before long. In some obstinate cases the concentrated acids—the nitric, sulphuric, and hydrochloric acids, have occasionally been employed as escharotics with advantage.

Favus of the hairy scalp, is an infinitely more rebellious disease than that of the trunk and extremities. The number of cases in which the simple warm bath, emollient fomentations and douches, alkaline or sulphureous baths, and washes of artificial mineral waters, might be employed with advantage, would be much more considerable, were we summoned to treat favus shortly after its invasion. General bathing, fomentations with linseed tea, and the application of emollient cataplasms to the head, after it has been carefully shaved, are very efficacious in removing old incrustations, and in lessening the redness of the skin, especially when the eruption is confluent; alone, however, these measures seldom accomplish a complete cure. This happy issue is less rarely brought about by the additional action of a couple of blisters applied to the arms, and kept open for two or three months. In the year 1817, I made a great many trials of this mode of treating favus, which is free from the dangers with which various other plans of treatment have been taxed.

In old standing cases of favus of the scalp, every method of treatment into which the avulsion or removal of the hair does not enter as an element is incomplete and unworthy of being entitled curative. The depilation in this case, is a measure as indispensable, as is the removal of the nail in certain varieties of onychia. This is the circumstance with which those physicians and surgeons have been struck, who have dwelt on different *depilatory methods of treating favus*.

The oldest system of this kind, consisted in tearing out the hair violently by means of some adhesive plaster, which was applied or spread over the scalp. To prepare this plaster, it was customary to mix four ounces of rye flour in a pint of cold white-wine vinegar; the mixture was set upon the fire and stirred continually, whilst half an ounce of the deuto-carbonate of copper (verdigrise) in powder, was added; it was boiled for an hour, after which, four ounces of black pitch, the same quantity of rosin, and six ounces of Burgundy pitch were added. When all these ingredients were melted and incorporated, six ounces of antimonial ethiops in fine powder (an alloy of mercury and antimony, obtained by long trituration), were thrown into the mixture, which was stirred till it had acquired what was held a proper consistency. The plaster thus prepared, was spread upon a stoutish black cloth, which was slit in different directions before being applied, to prevent it forming any crease, and to admit of its being subsequently removed in stripes.

The plaster was applied to the head, after having got rid of the incrustations by softening them with cataplasms, and having clipped off the hair as close to the skin as it could be done with scissors. After the lapse of three or four days, the plaster was removed rapidly the contrary way of the hair, and a second was put on, which was likewise removed in the same manner three or four days after its application. The plaster was subsequently renewed every second day, taking care to have the head shaved, when this measure appeared necessary. As may be conceived, and as was intended, these plasters each time they were renewed, tore out a quantity of hair more or less

considerable. The first applications were attended with cruel sufferings; the agony became less and less severe as progress was made in the treatment. Nevertheless, the pain was still so great at a month's end, that children might be heard screaming dreadfully when the plaster was removed; after the third month, the pain of the dressing became less intolerable.

It is undeniable, that by this method a certain number of cures were obtained, and these in severe cases, and after various other remedial measures had failed. But the action of the pitch-plaster cannot be kept confined to the diseased hairs only, and the avulsion of the healthy hair is both unnecessary, and extremely painful. In connexion with this procedure, I shall only add farther, that the Messrs. Mahon inform us, that they saw a child die two days after having had this horrible operation performed on its scalp.

With a view to avoid the extreme pain attending the process of tearing out a great many of the hairs in the same moment of time, we have been recommended to extirpate them one by one by means of a small pair of forceps contrived for the purpose.<sup>1</sup> But this procedure which lasts infinitely longer than the other, is in itself excessively painful when the hairs still adhere to their bulbs; and, indeed, can only be employed in those rare cases in which favus is confined to a very small portion of the scalp.

Of all the *depilatory* methods proposed, that of the Messrs. Mahon is unquestionably the best. The effects of their procedure are to cleanse the surface of the hairy scalp, to keep it in a state of the greatest freedom from all impurities, to modify the diseased skin in a very beneficial manner, to cause the fall of the hair without pain, and to be invariably followed by recovery.

554. The Messrs. Mahon begin their treatment by having the hair cut off at the distance of about two inches from the surface of the scalp; it is not made shorter, in order that it may be the more readily caught, and removed when loose, by the comb; the incrustations are got rid of by means of hog's-lard and poultices of linseed flour; the head is then washed with soap and water. The same process is repeated during four or five days in succession, or until the surface of the scalp appears quite clean. The second step is then taken in the treatment, the end of which is to accomplish gradually, and without the infliction of pain, the fall of the hair over all the places affected with favus. These parts are anointed every day with a depilatory ointment; and this application is continued for a longer or shorter time according as the disease is inveterate or more slight and recent. On those days on which none of the depilatory preparation is applied, a fine comb is passed repeatedly through the hair, which is found to fall out without pain. After this treatment has been continued for a fortnight, a few pinches of a depilatory powder are scattered amongst the hair once a week, the comb being carefully used to the diseased parts the day after, and a fresh quantity of the depilatory ointment applied. This procedure requires to be continued during a longer or shorter space of time according to the state of the disease. The same system is pursued during a month or six weeks, when more active depilatory agents are employed over the parts affected, every day for a fortnight, and subsequently twice a week so long as any redness of the skin remains.

555. Between the year 1807 and 1813 four hundred and thirty-nine individuals of the female sex, attacked with favus, were successfully treated according to this plan, at the Bureau central des Hôpitaux de Paris, the mean time of each case continuing under treatment being fifty-six days. During the same interval four hundred and sixty-nine boys were cured by the same means, the mean term of the treatment extending to fifty-three days. The hair was found to be regularly reproduced on those parts that were thus artificially made bald, when the progress of the disease had not destroyed the piliferous bulbs.

Numerous cases detailed in the books of the Bureau central, prove farther that favus which had resisted various other methods of treatment yielded to this. Among these are instances in which even the severest measures had been fruitlessly pursued for one, two, four, five, and even six years.

As a substitute for the *pommade épilatoire* of the Messrs. Mahon, the

<sup>1</sup> By Mr. Plumbe.

composition of which they have not made publicly known, the subcarbonate of potash or soda, in the proportion of one or two drachms to the ounce of hog's lard, may be advantageously employed, the affected parts being rubbed during ten minutes every day with this ointment. If the integuments appear considerably inflamed, the parts may then be washed with a solution of two drachms of the subcarbonate of potash in a pint of water, and the hair will speedily be detached without pain.

556. An immense number of topical applications, some of them almost inert, such as charcoal and the black oxide of manganese, others possessed of more or less active properties, such as poultices of hemlock, of mulberry-leaves, dulcamara, &c., ointments of cantharides, of the nitrate, and of the proto-chloride of mercury; blisters; solutions of the sulphate of zinc, sulphate of copper, sulphate of iron, deuto-chloride of mercury, and nitrate of silver, sulphuret of potash (1 dr. to 1 lb. of distilled water), and of the same salt combined with white soap, lime-water, and alcohol (R. potass. sulphuret dr. ii. sapon. alb. dr. i½; aqu. calcis ʒvii; alcoh. rectific. dr. i); the *Pommade de Banyer* (R. oxid. plumb. semivit. ʒiii, alum. calcin. ʒiss; proto-chlor. hydrarg. ʒiss adepis, lbs. ii; terebinth. venet. lb. ss); the ointment of the ioduret of sulphur, &c., &c., have all been recommended in the treatment of favus of the hairy scalp, but with such various and uncertain success, that none of them can be put in competition with the procedure adopted by the Messrs. Mahon.<sup>1</sup>(a)

(a) Of local applications in favus *confertus* or *porrigo scutulata*, Dr. Wigan (*Medical Gaz.*, 1843, and *Bullet. Med. Science*, 1844), declares concentrated acetic acid to be by far the best, and of itself all sufficient. He was not aware that Bateman, in one edition, refers, in a note, to the use of vinegar by Oribasius and Ætius, by the achores and in that brought out by Dr. A. T. Thomson, after speaking of the good effects of the application of sulphuric acid, he adds: "The acetic acid, or aromatic vinegar, which acts as a more gentle, yet very effectual caustic, has proved an effectual remedy in a few instances."

Dr. Wigan's method is thus described: "Unless the quantity of hair on the head is exceedingly small and offers no obstacle to the complete examination of the skin, I insist on the head being shaved very carefully, twice.

"The reason is obvious: with a moderate quantity of hair you may be curing the parts which first attract notice, while others which have been infected are gradually progressing to a visible disease, and the cure is thus indefinitely prolonged. I do not, however, object to a little circlet of hair round the face if there be no sign of disease apparent in it, and if it be carefully washed with hot common vinegar. This is a concession to parental vanity which may be safely made, and without which sometimes it would be impossible to obtain confidence.

"My remedy is Beaufroy's concentrated acetic acid—pyroligneous acid, as it is still called—though no longer made from wood.

"As a preliminary, however, I use the acid diluted with three times its weight of water. I call this the detector acid.

"On its application a number of spots which looked perfectly healthy become red patches. They are indications that infection had been taken, but had not gone through its stages, which period I believe (after great experience) to be eight days. This assertion is not lightly hazarded.

"Having by this reconnaissance ascertained the numbers and position of your enemy, your course is clear. One vigorous assault, and there is an end of the matter. With a picce of fine sponge, either tied to the end of a stick or held in a pair of silver sugar-tongs, I imbue each spot thoroughly with the concentrated acid for the space of three or four minutes, and the business is finished.

"The only reason why it is necessary to see the patient again, is, that as a crust is generally formed, and as an appearance of "worsen-

<sup>1</sup> Any plan which combines the removal of the hair by gentle means, that is to say, after it is already loosened from the roots, with undeviating attention to cleanliness for about two months, will be found generally to cure favus. I have seen more than one case of this disease get well by the regular use of simple soap and water, with the employment of the small toothed comb night and morning for a month or six weeks. Patience, perseverance, and cleanliness, are the sheet anchors in all the successful plans of treating this obstinate disease, as they are evidently in that pursued by the Messrs. Mahon.—R. W.

### Historical Notices and particular Cases.

557. Favus was long conjoined, and even confounded with different other chronic inflammatory affections of the hairy scalp, under the

ing" takes place, the friends require to have their confidence renewed from time to time by explanation and encouragement. I have often applied the acid more than once, but it was always (I firmly believe) unnecessary, when the preliminaries above stated had been gone through properly upon the shaved and tested head.

"The crust gradually grows up with the hair, which soon sprouts again if the eruption be recent, and as soon as a pair of fine scissors can be inserted underneath, it should be removed; but this should not be done prematurely, lest a sore place be produced.

"When first proposed, a good deal of correspondence took place respecting the plan with those who had tried it without success. I found, however, that in every case they had either used a much weaker acid (it is sold of all strengths), or that they had continued the use of it long after the disease was cured, and thus produce that not very rare result, 'disease of the doctor.' In the latter cases it was only necessary to discontinue the acid, and wash the head with warm water."

Certain new remedies in the treatment of favus and psoriasis are described by Mr. Wilson, and from his work I derive the following notices:—

"ON THE PREPARATION AND THERAPEUTIC VIRTUES OF ANTHRAKOKALI.—ANTHRAKOKALI was introduced by Dr. Polya, of Pesth, about two years back, as a specific in certain diseases of the skin, and was made the subject of a short treatise by Dr. Jacobovics. It was administered by Dr. Polya as an internal medicine, and was especially employed against tettery affections, which this gentleman conceived to originate in a peculiar constitutional disorder. Anthrakokali, in the hands of Dr. Polya, produced the same specific effects, in relation to the tettery principle, that mercury effects in the case of syphilis, sulphur in the instance of scabies, and iodine in that of scrofula.

"According to Dr. Polya, anthrakokali acts upon the entire system, producing a temporary increase of the local affection. It gives rise also to violent perspirations, and produces a general state of feverishness, under which the disease is cured. Thus it would appear, that by exciting a disease greater than that which it is employed to cure, it works its beneficial effects.

"On the reputation which this substance obtained in the hands of Dr. Polya, Gibert made trial of it in Saint Louis. Administered internally, he obtained none of the marked results described by its proposer; and after a fruitless experiment of several months' duration, gave it up as useless. Gibert next used anthrakokali as a local application, in the form of ointment: he found it less stimulant than the ordinary alkaline ointment, but yet sufficiently resolute. As a general principle, he remarks, 'the anthrakokali is a stimulant well suited to those cases in which we commonly employ sulphur and alkalies. It can only be used in the second stage of tettery affections—namely, in that in which the acute period has yielded to the chronic state, the latter being, nevertheless, subject every now and then to re-excitement.' For this reason, we find him lauding the effects of the anthrakokali, in a case of psoriasis inveterata, which had assumed an inflammatory activity under the use of an ointment of ioduret of ammonia. Thus, it would appear, that the anthrakokali deserves a place only among our more common stimulating applications, and is to be resorted to in cases where moderate stimulation is alone required, or where the morbid surface has become used to other forms of stimulant.

"My own practice is a complete corroboration of the results obtained by Gibert. I have not ventured to use the remedy internally, after perusing the account given of its effects by Dr. Jacobovics, but I have found it an ordinary stimulant as a local application. An additional stimulant is, however, often of considerable value in our treatment, after we have employed without success the forms which we are most accustomed to prescribe. I have frequently observed a morbid surface, which has remained unchanged for weeks under the use of a given resolute, suddenly assume a favourable aspect when treated by another with which the tissues are less familiar.

generic titles of *tinea* and *porrigo*. The translators of the works of Haly Abbas appear to have indicated favus under the name of *tinea*

"The mode of preparation of anthrakokali is as follows:—

R. Carbonate of potass . . . 180 parts  
Boiling water . . . . . 2500 "

After the solution of the alkaline salt, add hydrate of lime, in sufficient proportion to leave the potass free. Filter the fluids, and evaporate in an iron vessel until the surface assumes the appearance of oil. Then add 150 parts of coal in fine powder, stirring it with the liquid until it be well mixed. The iron vessel is then to be removed from the fire, and the stirring is to be continued until the contents are converted into a black homogeneous powder. The anthrakokali should then be placed in well-stoppered bottles, in a dry place, in order to exclude moisture.

"Dr. Polya also prepares a sulphuretted anthrakokali, by adding with the coal fifteen parts of sulphur also, in fine powder. This latter preparation is more active than the simple anthrakokali.

"Anthrakokali is deliquescent, and very soluble in water. Its solution is of a deep brown colour, throwing down a black flaky precipitate with a mineral acid. The colour of the solution of the sulphuretted anthrakokali is blackish-green.

"Dr. Polya asserts, that the anthrakokali is a chemical compound of potass and coal, and that in the form of solution, the latter is actually dissolved in the water. The test of this solution is the continuance of the fluid of its brown hue, without the occurrence of any precipitate. Gibert, however, denies this chemical combination, and regards it as a simple mechanical admixture. The coal, he says, separates from the fluid by precipitation, until the latter loses the whole of its colour, and none of the former remains behind.

"Dr. Polya prescribes two grains of the powder, three or four times a day in liquorice powder, or carbonate of magnesia. The ointment prepared by Gibert consists of

Axungia, 3j.

M.

To be applied with or without friction, as the case may demand, twice in the day.

"ON THE PREPARATION AND THERAPEUTIC VIRTUES OF FULIGOKALI.—Soot has long enjoyed a reputation as a stimulant remedy in chronic diseases of the skin; it has for many years been used as a popular application in diseases of the scalp, and very recently has been recommended with much praise in the treatment of favus.

"Fulgokali is a compound of soot and potass, in imitation of anthrakokali. It was first prepared by M. Deschamps, a chemist of Avallon, and has been made the subject of experiments, attended with considerable success, by M. Gibert, in Saint Louis. M. Gibert has employed the fulgokali both internally and externally, and finds it superior to anthrakokali. As an external application, in the form of ointment, it is resolutive, detersive, and stimulant.

"The mode of preparation of the compound is the following:—

R. Caustic potass . . . 20 parts  
Soot . . . . . 100 "  
Water . . . . . q.s.

Boil the mixture for an hour; cool, filter, evaporate, and dry. The fulgokali is obtained in the form of scales or powder, and must be kept in well-stoppered bottles in a dry place.

"A sulphuretted fulgokali is obtained by the following process:—

R. Soot . . . . . 60 parts  
Caustic potass . . . 14 "  
Sulphur . . . . . 4 "

Heat the sulphur and potass with a little water, and after their solution, add the soot. Evaporate, dry, and close the resulting compound in well-stoppered bottles, and keep it in a dry place.

"The ointment used by M. Gibert is composed of a scruple to half a drachm of the salt to an ounce of lard. In larger proportion it is highly irritating.

"Soot is a substance which is variable in its composition, and must differ according to the circumstance of being procured from the combustion of wood or coal. Its principal constituents are:—

Acetate, sulphate, and carbonate of lime,

lupinosa;<sup>1</sup> a denomination which has been adopted by Willan, who has described a second variety of favus, which appears in the shape of clusters or rings under the name of *porrigo scutulata*.<sup>2</sup> M. Alibert<sup>3</sup> has given a good description of favus, on the characters of which Messrs. Gallot,<sup>4</sup> Cooke,<sup>5</sup> Luxmore,<sup>6</sup> Plumbe,<sup>7</sup> and Mahon,<sup>8</sup> have published interesting observations. I have given a drawing of a remarkable case of this disease, in the atlas of pathological delineations illustrative of this work.

The seat of the eruption of favus has been placed by Fr. Bayle<sup>9</sup> in the subcutaneous cellular tissue, and with greater reason in the hair-bulbs by Astruc,<sup>10</sup> Murray,<sup>11</sup> and M. Baudelocque.<sup>12</sup>

An analysis of some of the secret remedies of the Messrs. Mahon, has been published by M. Braconnot.<sup>13</sup> Many cases of the disease have been detailed, and numerous remarks on its nature inserted in various periodical publications.<sup>14</sup>

CASE LXXXV.—*Favus in a child at the breast; treatment by Messrs. Mahon.* C. M. Charesse, aged three months, was brought to the *Bureau Central*, on the 14th of February, 1826. This child had been attacked with favus a month after her birth. On the left parietal region, there was an incrustation two inches in diameter, of a pale yellow colour, dry, prominent, presenting numerous cupped depressions, and evidently formed by the agglomeration of numerous favous scabs. There were besides several other incrustations of smaller dimensions on different parts of the head.

The child was in excellent health. Entrusted to the care of the practitioners mentioned, the incrustations and hair over the affected parts were removed within ten days, without any pain. The skin then looked red, dry, and shining, but free from sores or cicatrices. No fresh crop of pustules was developed, and a very short continuance of the treatment was found sufficient to complete the cure.

CASE LXXXVI.—*Favus cured by emollient applications and blisters.* A female infant, of very weakly constitution, and whose mother had died consumptive, was returned to its surviving parent, affected with scalled head, four months at least before the time at which I saw it.

Hydrochlorate of ammonia,  
Chloride of sodium,  
A brown, bitter, extractive matter,  
An empyreumatic tar,  
A bitter, volatile oil, possessing a strong odour of soot,  
A fatty matter, containing oleic and stearic acid,  
Carbon.

The potass solution dissolves the volatile principle of the soot, together with its aqueous extract. It contains, consequently, its active principles.

"It is probable that both the anthrakokali and the fulgokali owe much of their therapeutic value to the alkali which forms their basis. I have employed the fulgokali in several cases, and particularly in psoriasis palmaris, and with better success than I had obtained by the usual remedies."

On different parts of the hairy scalp, about thirty favous crusts could be counted. These were nearly half an inch in diameter, dry, of a pale yellow colour, prominent, with projecting edges and depressed centres; their superficial layers were whiter and more friable than their deeper parts, and they varied from one to several lines in thickness. The skin which surrounded them was neither red nor inflamed. Many of them were traversed by hairs. When they were detached, the corion under them was found red and slightly moist. Two small pustules existed on the parietal region, which scarcely passed the level of the integuments, and were covered with a slight scab on their apices. The head was shaved, and the affected regions covered with a linseed-meal poultice. The crusts soon became soft, and were easily removed; I bathed the tender parts regularly every day with a decoction of linseed. Before a week had elapsed, the surface of the scalp was rendered perfectly clean. I then applied a blister to each arm; these were kept open for three months. The fomentation was continued every day, and the favus was completely cured without any depilatory or other means than those mentioned, being tried. The blisters were then allowed to heal up, but in a very gradual manner.

CASE LXXXVII.—*Favus transmitted by contagion.*<sup>1</sup> An *Officier de Santé* was consulted in behalf of two little girls, whose cervical and sub-maxillary lymphatic glands were enlarged. He conceived that this state was induced by *tinea*, which had not been expelled from the system, and pursued a method of cure based upon this assumption. The poultices which had been applied to procure the removal of the incrustations of favus of the scalp, under which two sisters laboured, were actually applied to the heads of these poor children, one of whom was nine, and the other six and a half years old. These poultices were kept applied for a week, and were softened by being sprinkled every day with warm water, and covered with a fresh poultice externally; they became at length so offensive, that they had to be removed. On the sixth day, a number of small white pustules were perceived on the scalp of the younger child, which, on being pricked, discharged a whitish purulent fluid, and in the course of a few days, became covered with light gray scabs.

It was not till six days after the removal of the cataplasms, that a small red spot was perceived nearly at the distance of two inches from the incrustations mentioned. This spot, after a couple of days, was observed to be full of pus, which in concreting formed a very dry favous scab, the size of a millet-seed, circular in its shape, raised at its edges, and depressed in its centre;<sup>2</sup> it extended gradually, so as to be two lines in diameter at the end of eight days, and more than four lines after the lapse of two months.

The elder child did not contract favus; and the parents after a long perseverance in the poultices, perceiving that the enlargement of the glands did not disappear, consulted a physician, who prescribed a course of remedies adapted to scrofulous cases.

CASE LXXXVIII.—*Ulcerated favus; complications; death.* A. Courtet, aged three years, had been long affected with favus, when he was admitted to the Hôpital des Enfants malades, on account of pneumonia of both lungs, and a chronic affection of the cæcum and colon. The child was exhausted by this complication of diseases. He looked wan, and was emaciated to the last degree. Consumed by hectic fever, the child was evidently sinking fast. The favus, already of long standing, was in a state of ulceration, and a fortnight after his reception, he died. *Sectio cadaveris.* The hair is thin. On the surface of the scalp appear: 1, several favous incrustations well characterized, cup-shaped and very adherent to the skin, which is red, and inflamed beneath them; 2, a large incrustation on the top of the head, nearly three inches in diameter, prominent, presenting several cup-shaped depressions, and evidently formed by the agglomeration of several favous crusts; 3, in front of this larger incrustation, the skin presents a perforation nearly an inch in diameter. The subcutaneous structures in the vicinity of this perforation are destroyed, and to an extent so much the more considerable, as they are nearer to the bones of the cranium.

The sub-mastoid lymphatic glands are red and swollen. Petechiæ and ecchymosed spots are conspicuous over various parts of the body. The ventricles of the brain are distended with serum. The trachea and bronchi are flooded with a yellowish mucus. Both lungs are

hepatized. The mucous membrane of the large intestines presents a number of grayish spots, and that of the lower part of the rectum is affected with several ulcers; in the cellular substance behind, and to the right side of the gut, a small abscess full of grayish-coloured purulent matter is discovered. (a)

(a) *Cases of favus related by Dr. Carswell in the Lancet (1839).*—"Of the five cases of diseases of the skin to which I propose to direct your attention to-day, there are, as I have said, two of porrigo favosa, the only two cases of this kind we have had in my wards during the last six months. One of the cases was an example of the worst form of porrigo favosa; that is to say, of great extent and of long duration. The other was more limited, and of much shorter duration. There was no difficulty in recognizing the physical characters of the disease in either, although they were much more marked in the former than in the latter, both as to the cup-shaped appearance and colour of the pustules, and the patches formed by their extension and subsequent union. But as some of you may not be aware of what constitutes the elementary character of porrigo favosa, I may repeat what I stated on a former occasion, that this contagious pustular affection of the scalp consists in the presence of what is called the *favous pustule*. This pustule is formed by the deposition of a minute quantity of pus, which concretes almost immediately into a pale yellow or straw-coloured substance, having a defined circular edge, hardly, if at all, rising above the surface of the skin, and surrounded by a slight blush of red. The successive effusion and concretion of the matter proceed from the centre towards the circumference, in which direction they accumulate, and thereby raising the circular edge of the crust, and giving to it that *cup-shaped* appearance by which it is recognized. The size of these crusts or concretions, varies from one to two lines, to half or three-quarters of an inch in diameter. They are distinct at the commencement, but become confluent during their progress, and are sometimes confounded together into a large, dry, brittle mass, resembling a mixture of sulphur and plaster. Even in this state, however, of agglomeration, traces of the primitive or elementary character of the disease are perceptible, viz., numerous round or irregular depressions, indicating the situation and number of the original favi. The most of these appearances you will recognize in the description given of the following case of porrigo favosa.

"William Tobin, æt. eighteen, was admitted on the 6th of April. He is of a scrofulous habit and sanguineous temperament, and has enjoyed very good health, with the exception of headache, induced by the eruption on the scalp, which first appeared eight years ago, and has continued up to the present time, gradually getting worse, being attended with considerable itching and smarting, especially in warm weather.

"On admission, the head was the seat of an extensive eruption, occupying the upper, anterior, and posterior parts, and the patient stated that at one time it extended over the eyebrows. On all these parts the eruption does not present the same characters. On the upper, anterior, and lateral parts of the head, towards the temples, it presents the characters of porrigo favosa; over the occiput, those which bear a resemblance to the granular form of impetigo. On this part the hair is plentiful, but short and crisp, whereas on the former parts few traces of it remain. The most advanced part of the favus eruption presents patches, distinct from each other, five in number, and from one to two inches in diameter, of an irregular, but somewhat circular figure. The margin of each patch is uneven, thick, and elevated; its surface rough, dry, and fissured, of a yellowish-white colour, very much resembling a mixture of sulphur and mortar, more elevated in some parts than in others; of a loose texture, and in many places cellular, assuming the appearance of honeycomb. Besides these large patches, constituting the advanced form of the disease, and the result of the accumulation of the concrete secretion, and agglomeration of the original pustules, these latter are seen in a few situations, presenting their elementary characters; that is to say, they appear in the form of small, flat, straw-coloured pustules, quite distinct, with an elevated border, depressed centre, and slightly inflamed base. The intervening skin over a great part of the scalp is red, in several parts greatly congested, and traversed by numerous varicose vessels. There is considerable itchiness, but no great heat. Nume-

<sup>1</sup> Gallot. Rech. sur a teigne, 8vo. Paris, 1805.

<sup>2</sup> This spot (*bouton*) was certainly a pustule of favus.

rous large pediculi burrow in the fissures and sulci of the larger patches, and among the roots of the hair, on the posterior part of the head. The whole surface exhales an offensive and nauseous odour.

"The lymphatic glands of the neck and left axilla are greatly enlarged and very hard. The general health is pretty good; appetite very good; tongue clean; bowels regular; urine not albuminous; impulse of heart too strong and too extended.

"From the remarks I have made on the elementary characters of this form of pustular eruption of the scalp, you will readily recognize in the description of this case, the *porrigo favosa*. There is no other pustular eruption with which it could be confounded, except the *porrigo scutulata*; and here the mistake would be of little importance, as it is a disease of the same nature, similar in its elementary characters, arising, like the former, in the favous pustule,—communicable, like it, by contagion, and requiring the same means of treatment. The *porrigo favosa* is a disease which, when once seen, can hardly ever be confounded with any of the other and more common non-contagious pustular eruptions of the scalp; all its physical characters are so peculiarly well marked, and leave a defined and lasting impression on the mind. Those of you who have not seen this case when the patient was admitted, and before the incrustations were removed, may now obtain an accurate idea of the original appearance of the disease, so faithfully represented by Mr. Tuson in the wax model before you.

"The extent of the disease in this case, the great length of time which it had existed, and especially the extremely unhealthy condition of the scalp in general, were circumstances which combined to render the cure both tedious and difficult. It is easy to remove the incrustations, however extensive, by repeated poulticing; but the morbid condition of the tissue of the scalp, and of the bulbs of the hair, often resist, for a long period, the most assiduous and judicious use of remedies. It is not so much the reproduction of the original disease that retards the cure, as the repeated production of other pustular and vesiculo-pustular eruptions, the consequence of the diseased state of the skin. It is this latter, therefore, which we have chiefly to combat in bad cases of *porrigo favosa*, and to which, in this case, after the removal of the incrustations, the principal part of the treatment has been directed. After the application of poultices for two days, the scalp was completely cleansed of the incrustations. The hair was clipped short, and for some time the poultices were continued during the night, and the water-dressing applied during the day. Under this simple antiphlogistic treatment, considerable improvement followed, and was afterwards farther advanced by the occasional application of leeches to the most inflamed and congested parts of the scalp. With the same view, and also to diminish the tension and turgescence of the scalp, and effect the obliteration of the vessels with which it was so thoroughly penetrated, scarification, by means of a fine scalpel, was had recourse to, but could not be persevered in to any extent, in consequence of the great pain complained of by the patient. I expected to have derived great advantage from this method of treatment, which I have found extremely successful in chronic cases of circumscribed impetigo of this part of the body, accompanied by great thickening and vascularity of the scalp. It removes the tension of the affected part, diminishes the swelling, empties the enlarged vessels, and affords a free issue to the puriform secretion, which is either infiltrated, or exists in the form of numerous small abscesses.

"During the early progress of the case, copious eruptions of achorous pustules took place from time to time. This was occasioned chiefly by the use of the linseed poultices, and which always happens when not made of the fresh material. This occurrence, however, was obviated by using the potatoe poultice instead, the pustules which now make their appearance from time to time, being comparatively few in number. During the last two weeks, or more, these poultices have been applied at night, and a lotion of the subacetate of lead, or the simple water-dressing, during the day. Leeches, also, from eight to ten in number, have been applied several times, to the most inflamed parts, during this period.

"The improvement which has been effected by these antiphlogistic means has been very considerable; but there is yet much to be done to accomplish a cure of the disease. Although the tumefaction and

vascular turgescence of the scalp have nearly disappeared, there are still much redness and tension, which will require the same means of treatment for some time to come. When these morbid conditions have been still further reduced, and should we retain this patient a sufficient length of time in the hospital, as an in-patient, we may then employ, with advantage, various stimulating, or otherwise, modifying agents, such as alkaline and sulphureous lotions, the nitrate of silver, and other remedies of this kind, which experience has shown to be useful in the last stage of severe cases of *porrigo favosa*.

"In the treatment of this case we have not had recourse to the removal of the hair, recommended by several dermatologists, as a necessary part of the treatment of this disease. I am not disposed to attach much importance to this practice. At all events, the removal of the hair may be accomplished much more easily and speedily by the use of the alkaline ointment, or lotion, recommended by Biett, than by any of the means formerly employed. The ointment may consist of from one to two drachms of the sub-carbonate of potash, or of soda, to an ounce of hog's lard; and the lotion of the same quantity of these salts to a pint of water.

"I may remark, that the parts which were covered by the incrustations remain perfectly bald; the skin is quite smooth and glossy, and presents a somewhat reticulated aspect. Owing to the long duration and severity of the disease, there is no probability that the hair will ever be reproduced. In milder cases this sometimes happens, the new hair, however, having a somewhat woolly and crisp appearance.

"No general treatment has been employed in this case further than attention to the state of bowels, and the use of the iodide of potassium, which was indicated from the scrofulous enlargement of the lymphatic glands of the neck. It is doubtful whether any favourable change has followed its administration. If these glands are less hard than formerly, they are certainly not diminished in bulk.

"*Causes.*—I may say a few words on the supposed causes of *porrigo favosa*. It is, in itself, contagious, communicable by contact; but it occurs in many instances independently of this source, under a variety of circumstances, as to age, sex, and constitution. Biett states that its development is excited under a variety of circumstances, such as a deficiency of the necessary articles of food; misery and filth; living in unhealthy, ill-aired, damp situations. That it occurs chiefly in persons of a soft, lymphatic, and highly scrofulous constitution, although it may be met with in young persons presenting all the attributes of health and strength. Under such circumstances, it is obvious that we are, as yet, ignorant of the real cause of this disease, as well as of that state of the constitution which renders individuals susceptible of its contagious influence; for it is not always transmissible by contact, as has been proved by experiment; and many boys in the same school, equally exposed with those who contract it, escape altogether free from it.

"The second case of *porrigo favosa* is a good example of the disease, occurring in an otherwise healthy child, of five years of age. We have not been able to obtain a full history of the case. The father is said to have had a scorbutic eruption on the face. A brother and sister have had eruptions on the head, but the precise nature of them has not been ascertained.

"The eruption in this child had existed nearly five months, and he was treated for some time as an out-patient. When admitted into our wards, a number of favous pustules, and patches of incrustations, of a pale, yellowish-gray colour, of a brittle consistence, the largest not more than the fourth of an inch in diameter, occupied the upper and posterior parts chiefly of the scalp. They were accompanied by very little redness of the surrounding skin; no exudation, or other morbid appearance of the rest of the head. The general health was good; there was no enlargement of the abdomen, no derangement of the digestive organs; appetite good; sleep natural.

"The elementary characters of the *porrigo favosa* were readily recognized in this case, although not so marked as in the former one. Several of the pustules presented the depressed centre and elevated border; and the incrustations, the dry, plastery look and colour peculiar to them.

"The favourable state of the general health, the limited extent of the disease, and the absence of inflammation of the scalp, except in

## ECTHYMA.

Vocab. *Ecthyma, Phlyzacia* [Papulous Scall].

558. Ecthyma is a non-contagious inflammation of the skin, characterized by largish prominent pustules, seated on a hard, circular, bright-red base.

These pustules, entitled *phlyzacia* by Willan, are almost always distinct, and usually make their appearance in succession, on one or several regions of the body. When they dry up they become covered with thick brown-coloured and adherent crusts: these, after their fall, leave red marks on the skin, the centres of which very commonly present a small cicatrice.

Willan has described four species of ecthyma: *ecthyma vulgare*; *ecthy. infantile*; *ecthy. lividum*; *ecthy. cachecticum*; founded on the various appearances of the eruption, the intensity of the accompanying inflammation, the more or less rapid progress of the pustules, and the state of constitution of the individual affected. These modifications of the disease do not, however, seem to me, to be adopted on grounds sufficiently stable to give them a title to be recognized at the present day as more than mere varieties, and I prefer the simpler and more practically useful division of the disease, into, 1st. *acute*, and 2d. *chronic* ecthyma.

559. *Symptoms.* Ecthyma occurs on every region of the body; but it is principally observed on the shoulders, neck, extremities and breast; it very rarely appears on the hairy scalp. I have seen it forming a kind of belt round the trunk. It occasionally invades almost the whole surface of the body, but is much more frequently confined to a single region.

560. In its most simple, but also rarest shape—that, namely, which is *acute*—ecthyma is proclaimed on some region or regions of the body, (those of the neck and shoulders most frequently,) by large, distinct, hard, conoidal, and painful red elevations, the size of which varies between that of a lentil, and that of a large pea. Their base, which is of a vivid-red, spreads at the same time that the prominence of their summit increases. A purulent point is before long seen in their centre. In this state, the larger pustules bear a considerable resemblance to small boils. When suppuration is fairly established, they often present a little black point, which at a later period is succeeded by a larger brown-coloured crust, very adherent to the skin, and set or incased as it were within its substance. The eruption of the pustules of ecthyma is completed within a few days.

In this mild form of ecthyma, to which the species entitled *vulgare* by Willan, belongs, the crusts are detached within a week or two. After their fall, a few marks, from six to eight lines in diameter and of a livid-red colour, remain on the skin, in the centre of each of which a small cicatrice, having some analogy to that of a small-pox pustule, but differing from it in being shallower, is usually perceived.

On a careful examination of the structure of the pustules of ecthyma at different periods of their development, we find 1, that in their first stage (*red elevations*) there is merely sanguineous injection, with conical tumefaction of the corion; 2. that in the apex, more rarely

the immediate vicinity of the patches, were circumstances which augured a speedy, and, probably, permanent cure of the disease. The incrustations were removed by poultices, and the head cleansed by frequent ablution with warm water and soap. The alkaline ointment was afterwards used for some time to effect the removal of the decayed hair, and also to stimulate the less inflamed parts of the diseased cutis. And, lastly, the nitrate of silver was applied to those points where fresh pustules appeared, or where the skin was excoriated. No trace of the eruption remained at the end of six weeks, except complete baldness of the parts which the former had occupied. Full diet was allowed, and the bowels were regulated by occasional small doses of calomel and rhubarb.

"The success which followed the use of the nitrate of silver in this case, was partly attributable to the circumstance of the disease having ceased to spread, although it certainly also arrested the development of several pustules which appeared during the progress of the treatment."

over the whole surface of the elevations, and under the cuticle, there is an effusion of a certain quantity of purulent serum; 3, that in the third stage, which follows immediately after, there is a kind of pseudo-membranous matter deposited in the centre of the elevation, which is now evidently perforated; 4, that after the voidance of this matter and the removal of the cuticle, the pustule appears under the form of a cup-shaped cavity, surrounded by a hard, thick, puffed edge; 5, lastly, that on the following days this thickened margin subsides, at the same time that a slight cicatrice is formed under the crust, the centre of which is fixed within the point where the perforation had been observed.

When the pustules of ecthyma are coherent, a circumstance that happens but rarely, two pustules thus conjoined may seem to form only one, the circumference of which is irregular in its shape. The epidermis is then raised over a large extent of surface; and if, after having removed this, the purulent serum, with which the epidermis is bathed, be wiped away, two circular and contiguous borders are perceived, in the centres of which a small perforation with a false membrane at the bottom is distinguished.

The development of the pustules of *acute* ecthyma is accompanied by rather severe pain of a lancinating kind, especially when the pustules are clustered upon a single region of the body. The pain in this case seems analogous to that which usually precedes and accompanies shingles. The lymphatic glands in the neighbourhood of these pustules are occasionally swelled and painful.

The pustular inflammation of ecthyma may be preceded or complicated with disorder in the functions of the digestive organs, which occasionally continues after the cure of the disease. It is seldom that this variety of ecthyma is accompanied with fever.

561. *Chronic* ecthyma is a much more common disease than that which has just been described, and consists in several successive eruptions, which appear on the neck, extremities, and occasionally even on the face, at intervals more or less remote from each other. Each of these eruptions presents features in its course analogous to those which distinguish *acute* ecthyma. Whilst several of the pustules are appearing under the form of large red elevations, others are suppurating, and others are drying off and cicatrizing. It is not uncommon for several eruptions of such phlyzacious pustules to take place over different regions of the body within the space of a few months.

Besides this particular mode of making their appearance, the pustules of chronic ecthyma occasionally exhibit peculiar characters. In persons advanced in life, of indifferent constitution, affected with ulcers, &c., very large pustules are occasionally observed to be produced, with bases very similar in appearance to those of furuncles. The voluminous elevations which signalize their earliest stage, have a deep red tint from their first appearance; the skin swells very slowly; the cuticle, distended with a blackish or sanguinolent serum, gives way at the end of six or eight days; the centres of the elevations soften, and become covered with a thick crust, which is prominent, black, very adherent, set, as it were, within a rim of the skin, and is not loosened before the lapse of several weeks.

When this crust is accidentally detached, or when it is removed by means of topical applications, it is found to conceal a small ulcer. Left to itself, this ulcer hardly becomes covered with a fresh scab; its surface discharges a sanious fluid.

These small ulcers may continue open for a very long time, and even spread, especially when they are situated on the lower extremities. When they are at length healed up, they leave cicatrices behind them, which long continue of a livid or violet colour.

In weakly and ill-fed children, attacked with chronic inflammation of the abdominal viscera, or convalescent from small-pox, this variety of ecthyma (*Ecth. infantile*, Willan) is frequently observed with this peculiarity, that the pustules are generally of very inferior size.

562. When there exists but a small number of pustules on the surface, when several successive eruptions have taken place at intervals rather remote from each other, and the disease is altogether uncomplicated, chronic ecthyma is not accompanied by morbid symptoms of a general nature. The rather frequent complication or coincidence of chronic inflammatory affections of the thoracic and abdominal viscera with ecthyma, among children and the aged of

indifferent constitution, explains the circumstance of the generality of authors having spoken of such symptoms as anorexia, pain of the epigastrium, irregularity of the bowels, cough, headache, pains in the limbs, sense of lassitude, loss of muscular strength, &c., as forming part of the disease when it attacks these two classes of subjects.

Willan and Bateman have mentioned concomitant inflammations of the conjunctiva and mucous membrane of the pharynx; but I am led to believe that the greater number of the ecthymas of this description of which they speak, were due to a syphilitic cause (Vide syphilitic *phlyzacia*).

Ecthyma occasionally occurs during the exacerbations of lichen prurigo, scabies, and several other chronic inflammations of the skin; and the disease is a very frequent attendant upon convalescence from small-pox.

The continuance of chronic ecthyma, dependent on the number of successive eruptions that take place, and the state of the constitution, occasionally extends to a period of three or four months. The concomitant affections, if any exist, may get well before the pustules or continue after their disappearance.

563. *Causes*.—Ecthyma attacks individuals of every age and of every variety of constitution; (a) it occurs at all seasons, but is met with more particularly during spring. A cold and damp habitation, filthy clothing, and indifferent food are causes common to this and a great number of other affections of the skin. Ecthyma is not a contagious disease, and its appearance may correspond with a disordered condition of the functions of the stomach and bowels.

564. *Diagnosis*.—Whether ecthyma be acute or chronic, and consist in one or several successive eruptions, its voluminous and prominent pustules present characters which at all times prevent their being confounded with the other diseases of the skin. Mistake is impossible when its large pustules are compared with those of impetigo, of rosacea and of favus. When the pustules of acne and of sycosis present a large, hard, and red base, they might more readily be taken for pustules of ecthyma; but the pustules of the two former are evolved on indurated rather than on inflamed bases, and their modes of development and termination are very different from those of ecthyma.

The pustules of ecthyma are neither umbilicated nor contagious, like those of variola and vaccinia.

Ecthyma occurring in unhealthy subjects, might be readily confounded with a certain variety of pustular syphilis (ecthyma *syphiliticum*). This uncertainty, however, can only occur in those cases in which the eruption of the pustules of ecthyma has taken place in a slow and successive manner (*chronic ecthyma*). Further, *syphilitic phlyzacia* are seldom surrounded by an areola so broad as the pustules of ecthyma; the colour in each class of pustules is also different, being of a purplish or livid red in ecthyma, and commonly coppery in the syphilitic affection. The scabs of syphilitic phlyzacia are usually of considerable thickness, frequently nearly black and almost uniformly circularly furrowed. The ulcers that succeed them are deep and excavated, and are constantly followed by depressed and indelible cicatrices. Lastly, it is very seldom that syphilitic pustules are not accompanied by other venereal symptoms calculated to throw light on their true character; without these, indeed, the real nature of many phlyzacious eruptions would frequently remain obscure, especially when they are developed among the cachectic and ruined in constitution.

The small pointed pustules of scabies have no analogy with the

(a) The majority of cases of ecthyma occur in young men, who, with constitutions originally not of the strongest class, had imprudently indulged in excesses and irregularities to a very great extent, accompanied by privation of rest and other depressing circumstances. Very frequently in such cases it is mistaken for a venereal eruption, and the patient himself is readily made to believe in an opinion which his habits have made so probable. If mercury be had recourse to, under these circumstances, the disease is much aggravated, the dried scabs of which it is constituted grow on the part rapidly, becoming of a dark-brown colour, exceedingly hard and of a conical form, representing in fact, on a minute scale, the characters of the disease termed Rupia. Plumbe (*op. cit.*, p. 303).

large pustules of ecthyma; when these two eruptions occur accidentally in the same individual, it is always easy to detect the complication.

565. *Prognosis*.—The prognosis in ecthyma varies according to the number of eruptions, the state of the constitution, the nature and gravity of the concomitant lesions, the age of the patient, the evident possibility or impossibility of removing from beyond the influence of the causes that appear to have produced the disease, &c. *Acute* ecthyma always gets well in the course of two or three weeks; *chronic* ecthyma may continue for many months.

566. *Treatment*.—If the eruption in acute ecthyma is confined to a few scattered pustules, and exists without complication in an individual otherwise well constituted, diluents must be prescribed, the use of the simple cold or temperate bath enjoined, whilst a regular and unstimulating plan of life is pursued. If the eruption proves more copious, and is attended with much pain, if it appears complicated with furuncles, and the individual affected is young and vigorous, a general bleeding should be practised, and the cool and temperate bath repeated more frequently.

The health of those who are labouring under chronic ecthyma having frequently suffered from various other inflammatory affections of long standing, these are the serious diseases, the grave disorders of the constitution which it is of the last consequence to watch and attempt to subdue. A light, nutritious and restorative regimen, suited to the state of the digestive organs and of the constitution; aromatic or sulphureous baths prolonged in various degrees, and repeated two or three times a week, or alternated with baths of some saline mineral water, added to tonic and chalybeate medicines internally, must form the elements of the curative plan in such complicated cases.

When chronic ecthyma appears in an infant at the breast, it is of the highest importance to ascertain the qualities of the milk it is receiving; a change of the nurse may become essential to ensure the success of the general therapeutic means employed; this measure alone, indeed, frequently suffices to give a favourable modification to the constitution, and, as a consequence of this, to cure the complaint.

The ulcers which chronic ecthyma occasions when it attacks the lower extremities of elderly persons, have generally an unhealthy appearance, and are very slow in getting well. It is often found necessary to stimulate these by touching them with the nitrate of silver, or by bathing them repeatedly with some aromatic decoction, by using a solution of the chloride of lime as a wash, or powdering them with cream of tartar. (a)

#### *Historical Notices and particular Cases.*

567. The word *ecthyma*, employed by Hippocrates,<sup>1</sup> in a sense which the translators have interpreted by the Latin *pustula*, is applied in many passages to eruptions, the description of which is so incomplete that by some they have been held to be small-pox, by others a species of typhoid exanthema.<sup>2</sup>

Willan was the first modern writer who gave the title of ecthyma to the disease that has just been described, the characters of which he has portrayed with great distinctness. But few cases of the disease are to be found in our periodical publications. Several incomplete accounts of *eruptions of a great number of small furuncles*; of *pustular and crusted tetter* (dartres); of *a singular disease of the skin*, &c., give mere occasional glimpses of one or two of the characters of ecthyma.

(a) Deprived of the use of mercury in ecthyma, for reasons assigned in the text, we can, in requital, have recourse to an alterative scarcely less diffusive and searching in its operation, and yet safe in its general and ultimate effects. Iodine is the article to which I refer. Its salt the iodide of potassium, and in the more decidedly cachectic or chronic forms of the disease, the iodide of iron will meet the desired indications. As a topical remedy the ointment or the liniment of the iodide of potassium, will come in aid of the substances mentioned in the text.

<sup>1</sup> Hippocrates. Epidem., lib. iii.

<sup>2</sup> Forstus. De febri pestilente in qua ecthymata et exanthemata apparebant, lib. vi. p. 240.

I subjoin a few particular cases of the disease, and several others may be found in the dissertation of M. Asselin.<sup>1</sup>

CASE LXXXIX.—*Acute ecthyma of the scalp.* A young woman, after feeling the hairy scalp excessively itchy for some days in the beginning of August, 1820, was attacked in this part with *ecthyma*. Large *phlyzacia*, containing a purulent fluid, were evolved over the entire surface, and especially on the frontal and occipital regions of the scalp. This inflammation was attended with painful swelling of the lymphatics of the neck. The pustules were not visible except when the hair was parted. After continuing for seven or eight days, they all became covered with crusts, which, on falling off, discovered brown and violet-coloured marks on the surface of the skin. The integuments in every other situation were perfectly healthy (*Venes. ad 3viii; infusion of endive for drink*); after the lapse of a week *cight leeches* were applied around the back part of the neck, and three doses of purgative medicine were subsequently prescribed at intervals of four days; at the end of a month no traces of the disease remained, except a number of violet-coloured marks in the situations which had been occupied by the pustules.

CASE XC.—*Successive eruption of large ecthymatous pustules on the left lower extremity; pulmonary catarrh.* Antoine, forty-two years of age, consulted me on the 1st of March, 1826, on account of some large pustules with inflamed bases, which had appeared three weeks before on his left thigh.

On the 10th, the following circumstances were observed: 1. A very large pustule near the inner condyle of the femur, covered on its summit with a small black point. This pustule, with its areola, is nearly three-quarters of an inch in diameter. 2. Another still larger pustule, on the fore part of the thigh, the suppurating surface of which is from three to four lines across, whilst its base, formed by a broad areola, is hard, tumid and deep. These pustules are the seat of severe lancinating pains. On the fore part of the thigh there exist a dozen spots or marks, of a reddish-brown colour and circular shape, which have been produced, according to the patient's account, by the pustules that first made their appearance.

The patient complained of nothing save of a slight pulmonary catarrh, which had not prevented him from following his business of a hat-maker; (*mucilaginous drink; the warm bath; magnes. sulph. 3ss.*) This prescription was repeated three times in the course of six days. The tops of the pustules became covered with yellowish-brown scabs. The warm bath and mucilaginous drink were continued for a week. The crusts were detached without the expulsion of any sloughy core, and left two small cicatrices on the skin surrounded by a dusky violet-coloured areola. No fresh pustules were thrown out.

CASE XCI.—*Ecthyma; successive eruption of phlyzacious pustules on the left forearm and nucha; cæco-colitis.* On the 20th of March, 1822, I had a little girl, eleven years of age, brought to me, on account of a number of pustules which had made their appearance on the left forearm. They were in different stages; three were nascent, and consisted in mere red and papular-looking elevations, surrounded with broad areolæ; five were in the state of true phlyzacious prominent pustules, and about three-quarters of an inch in diameter, including the areolæ. Their bases were hard and deep, their summits filled with a purulent sanies. One was excoriated, from having been torn by the patient with her nails. Three others of the same size, surrounded with dusky areolæ, were covered with prominent scabs of a greenish-brown colour, and very adherent to the skin. These pustules were affected with shooting pains of considerable severity. Three violet-coloured marks were also visible on the skin, less depressed than those of small-pox, but about the same size. This eruption was unaccompanied with fever; the tongue was clean, the appetite good; yet the abdomen was distended and tympanitic; and for the last eight or ten days, four or five liquid dejections had been passed every four and twenty hours. Slight pressure in the course of the colon evidently occasioned pain (*six leeches to the verge of the anus; mucilage; tepid bath of an emollient decoction; diet; beef-tea with bread*). The intestinal symptoms yielded to this treatment in little more than a week. The nascent pustules

advanced; the scabs of the others were detached. A fortnight after her first visit, a fresh crop of five or six pustules made its appearance, one of which acquired such dimensions, that at first sight it might have been mistaken for a boil. The treatment was continued, and these pustules declined like those that had gone before them. The disease seemed ended, when a third eruption made its appearance on the nape of the neck, and in the course of the next fortnight many phlyzacious pustules were successively evolved on the occipital region of the scalp. Some of the lymphatic glands of the neck inflamed; the affected parts were painful, and the sleep of the patient became disturbed (*tepid mucilaginous baths every other day; cataplasms of mallows to the nucha*). Three weeks of this system sufficed to put an end to these symptoms; the pustules disappeared, leaving small violet coloured spots behind them, and the little patient got quite well.

CASE XCII.—*Ecthyma cachecticum; phlyzacious pustules successively developed on the forehead, trunk and extremities; tympanitis.*<sup>2</sup> "J. H., aged twenty-three years, a sailor, was admitted into the Pennsylvania Hospital on the 7th of May, 1825. He stated, that, in the month of February, while in Havana, without his having experienced any constitutional indisposition, he was suddenly affected with an eruption on his forehead. It commenced in the form of small pustules, the summits being of a whitish colour, the bases red and inflamed. The disease successively extended to other parts of his body, affecting the trunk and the extremities; his hands, feet, and the flexures of the joints, however, remained perfectly healthy. At the period of making the record, it is stated, that in some instances, the pustules had been converted into dark brown scabs, of various extent, from one-eighth to half an inch in diameter. This was particularly observable on the forearms. On the breast, the pustules presented the character of concreted pus, and had not assumed the brown colour. On his forearms, the skin surrounding the eruption was generally inflamed, and of a dark cochineal red. On the breast, the hue was more various, affording all the shades from the light lake to the dark cochineal red. On this part of his body there was noticed a discoloration of the skin, resembling the pityria of Willan; and spots of a colour between the ash and pearl-gray, were perceived more especially upon the trunk, which were supposed to be cicatrices, the seats of former scabs that had desquamated. At the period of his admission, his ankles were swelled, and we observed tumefaction and tenderness of the gums, from which there occasionally issued a little blood. His muscular strength was impaired; his appetite was good, and his alvine discharges regular; his skin was warmer than natural, and dry; his pulse 100, small, and wiry. He was put on the free use of fruit, and fresh lemon-juice, and his body was regularly washed with warm water and bran.

"From this treatment, on the 25th of May, there was an apparent improvement in his general health; his skin had become soft and of natural temperature; his pulse 100, and no longer wiry. He had, however, suffered more hemorrhage from his gums, which had been restrained by a gargle of myrrh. Many of the scabs had fallen off, leaving slight depressions, at first, of a faint red colour, and which afterwards became of an ash or pearly-gray, as expressed in the first report. He was now directed to take a fluid drachm of the tincture of sulphuric acid, with a pint of an infusion prepared with quassia, serpentaria and orange-peel.

"On the 1st of June, the eruption had nearly disappeared from the forehead. On the trunk, and the extremities, more of the scabs had fallen off, and the colour of the skin had considerably faded.

"On the 8th of June, though the eruption was evidently disappearing rapidly, it was deemed necessary to vary the prescription, in consequence of the man's having become tympanitic. His abdomen was tumid and elastic, and afforded no fluctuation on percussion. He stated that the distension was most obvious in the morning; that he was much troubled with flatulence, and that he experienced great relief, accompanied by an evident diminution of the swelling, on the discharge of wind. His urine was natural, both in colour and quantity; his bowels open; his tongue clean; his pulse 100, and feeble. He was now directed to take the carbonate of iron and the resin of guai-

<sup>1</sup> Asselin. *Essai sur l'ecthyma*, 4to. Paris, 1827.

<sup>2</sup> Thos. T. Hewson, M. D. *Case of ecthyma cachecticum*. (North Amer. Med. and Surg. Journ., Jan., 1826.)

cum; of each ten grains, with five grains of powdered capsicum, three times a day, instead of the acidulated bitter infusion. The ablutions with warm water and bran were continued. These means operated beneficially; the tympanitic affection subsided; the scabs continued to fall off; and a considerable portion of the skin had resumed a healthy colour. On the 15th, however, in consequence of his bowels being very frequently disturbed, it was deemed advisable to substitute ten grains of powdered gentian, in the place of the resin of guaiacum. In this form the medicine was continued until the 22d, when he requested permission to leave the hospital; at which period he was reported to be nearly well."

"The case I have recorded, will be readily recognized as the *ecthyma cachecticum* of these writers. In some features, shades of difference will be perceived, perhaps not essential, but only indicating an individual variety, and, probably, dependent on the same disordered state of the system. The *pityriasis* which I have noticed, has been frequently observed, in connection with slight disturbance of the constitution; and is by no means incompatible with that condition which is found to precede and to accompany the eruption of *ecthyma*. The spots, of a pearl or ash-gray colour, which appeared on the desquamation of the scabs, have not been described by those who have written on the pustular diseases of the skin; nor do I recollect to have observed such before. They may, therefore, be deemed purely accidental, or as marking some peculiar condition of the skin in the individual whose case has been noticed. Slight febrile symptoms are generally observed to usher in the first appearance of the eruption, and some degree of hectic or erethism accompanies the progress of the disease. Languor, depression of spirits, and prostration of the muscular powers, are ranked among the accompanying symptoms. Weakness of the digestive organs is likewise a usual attendant. In this man, the appetite is stated to have been good; yet the tympanitic affection of the bowels affords sufficient evidence, that the function of these organs was imperfectly performed. The swelling of his ankles, and the hemorrhage from his gums, exhibit proof of a depraved condition, approaching to scurvy. The duration of the disease corresponded with general observation, two and four months frequently elapsing before the cure can be effected.

"The previous history, or a knowledge of the causes leading to the production of the disease, cannot be collected from the present case. Very particular inquiries were made; but with all their general reputation for frankness and candour, we often find sailors little entitled to confidence, in the narrative they give of their real habits, or of the places they have frequented. This defect of evidence excited in some who witnessed the case, strong suspicions of its connection with a syphilitic taint. Against this error, it is of importance to guard; for too many persons affected with such eruptions, have been subjected to repeated and unavailing courses of mercury. That syphilis, in its secondary forms, ever assumes the character of *ecthyma*, has been denied by some very intelligent practitioners; and it will be readily conceded by every man of experience, that the diagnostic signs of the syphilitic forms are extremely equivocal, and that, in most instances, *ecthyma* can be traced to causes totally independent of such contamination. Though frequently observed in persons whose constitutions have been impaired by the previous ravages of the disease, or by the debilitating processes employed for its removal, it yet remains to be proved that the appearance of *ecthyma* can be essentially traced to a syphilitic origin. Should the alliance be established, we may hope, from the prevailing spirit of investigation, and from the minute attention paid to pathological distinctions, that the discriminating characters will not remain veiled in obscurity. From a careful perusal of the best writers, and from attentive observation in the treatment of *ecthyma*, I am inclined to believe, that in most instances, the cure will be most speedily accomplished without the use of mercury, though this mineral constitutes one of the most efficient remedies in certain defecations of the skin. Where there exists a discrepancy of opinion among those whose experience is entitled to respect, it is incumbent on us to examine scrupulously, and to weigh all the circumstances, in order to attain an accurate knowledge of the curative indications to be fulfilled.

"Under the impression, that the production of *ecthyma* is connected with a state of cachexia, our efforts will be directed to the

removal of this condition, and to the imparting of a due degree of tone and vigour to the system. To this end, on many occasions, a regulated diet, consisting of such articles as afford a nutriment bland and easy of digestion, will prove sufficient. At the same time, attention should be paid to personal cleanliness, in the use of the tepid bath; or this purpose may be conveniently accomplished by frequent ablutions with warm water and bran. With the same intention, we find various farinaceous decoctions, and water impregnated with vegetable mucilage, as obtained by boiling the bark of the slippery-elm, highly recommended. These topical means facilitate the desquamation of the scabs, and by softening and cleaning the cuticle, assist in restoring the skin to a sound and healthy condition.

"When the strength has been more deeply impaired, benefit will be derived from the administration of the vegetable tonics; as, the decoction of cinchona, serpentaria, sarsaparilla, &c., either simple, or in the more compounded preparations. To these, the mineral acids are often advantageously added. I have lately visited a patient, affected with the disease, after a severe attack of typhus. The man's face was greatly disfigured, and he was rendered a most loathsome and disgusting object. In this case, yeast, exhibited to the extent of a pint and a half daily, has afforded the most positive relief, acting as a grateful cordial; while the mildest officinal bitters, and the conserve of roses, excited intolerable distress, in consequence of the extreme tenderness of his mouth and throat.

"In persons labouring under constitutional irritation, the decoction of sarsaparilla, in combination with antimonials, has proved eminently serviceable. But on many occasions, our chief reliance must be placed in the free exhibition of opium, cicuta, stramonium, or other narcotics.

"In the more protracted forms of *ecthyma*, change of air and gentle exercise will contribute essentially in strengthening the system, and in shortening the disease." (a)

(a) In place of an abridgment of this case, I have inserted the original paper by Dr. Hewson, with the omission of a few remarks on the terminology of the disease.

The following case is given by Dr. A. T. Thomson, in his edition of Bateman's Synopsis:—"The patient, an unfortunate German gentleman, having fallen ill of a fever, lost all his employment, and became so depressed both in mind and body, that he sunk into a cachectic state of habit, and was soon attacked with *ecthyma*. He applied to me on the 27th of June, 1828, two months after the disease had made its appearance. The eruption covered the whole of the body, with the exception of the hands and the face. The stinging sensation was also accompanied with itching, or rather a tingling, which induced an involuntary desire to scratch, by which not only the heads of the pustules were rubbed off, but large portions of skin, in some places two inches in length, and nearly an inch in breadth, were torn off by the action of the nails during the sleep. Those pustules which had run their course had left dark stains behind, so that the greater part of the entire skin was covered with these and the crusted pustules. When the pustules were early rubbed, black dots of effused blood remained. The thighs were covered with ulcers. The body was greatly emaciated; there was a regular evening exacerbation of fever; the tongue was clean, but red and glazed; the skin felt dry and harsh; and the patient stated that the delirium attending the fever and the depression of mind had driven him nearly to commit suicide. The bowels were irregular. The following medicines were ordered:

 ter quotidie.

## PUSTULES PRODUCED ARTIFICIALLY.

568. Different substances, when inoculated or applied to the surface of the skin, may cause the development of pustules of various forms and dimensions. Several of the eruptions thus artificially excited, have been made the subjects of particular study by more than one pathologist.

569. *Pustules from the inoculation of animal matters.* The title of *spurious variola* or *false small-pox* used formerly to be applied to those pustules which followed the inoculation of variolous matter which had become altered or deteriorated by drying, keeping, &c., which in a word, had lost its contagious and specific properties. Pustules of a like description, engendered by the inoculation of the vaccine virus which had lost its peculiar properties, have since been entitled *spurious cow-pox*. The pustules thus excited have, however, no analogy with the pustules of small-pox or of cow-pox; on the contrary they bear a great resemblance to the pustules that follow wounds with a rusty instrument, impregnated with some irritating animal matter. These pustules usually get well spontaneously in the course of a week or two. They occasionally end in ulceration when they have been irritated by the neglect of proper cleanliness or the application of stimulating local applications. By touching their apices with nitrate of silver, the inflammation of their bases is lessened, and their cure is expedited.

570. *Pustules from the external application of certain vegetable substances.* Several vegetable substances, externally applied, have the property of exciting accidental pustules which either appear alone or complicated with vesications and papulæ. A patient of mine, affected with dropsy, for whom I had prescribed the inunction of half a drachm of the extract of aconite incorporated with half an ounce of lard, was attacked soon after commencing the use of this application with an

"When the irritation is severe, let the surface be sponged with hot water. Let the diet be milk, fresh-boiled vegetables, and a moderate share of mutton under-cooked.

"July 5th.—Few fresh pustules have appeared; and the dark colour of the blotches is much less. The new pustules contain a mild pus. The bowels are regulated by the aperient; and although the fever still returns every evening, yet the delirium which attended it has disappeared. He feels, occasionally, as if a cloud had settled upon him, and cut him off from all external impressions. The tingling and irritation are less, and return only in paroxysms, during which he still tears off large portions of the skin.

Cont. medicamenta.

R. Plumbi acetatis ʒss;  
Acidi hydrocyanici fʒiij;  
Ung. cetacei ʒiij. M.

Fiat unguentum partibus cutis nudatis applicandum.

"18th July. He is much better in every respect, and the irritation is so much abated, that he can now sleep without excoriating his body. He is gaining both in flesh and strength.

Perstet in usu medicamentorum.

"August 2d.—The eruption is nearly gone, and the skin is regaining its natural aspect. He complains of watchfulness, and great depression; but the want of employment and distress of mind seem to be counteracting the full powers of the medicines.

Cont. medicamenta.

R. Camphoræ gr. v;  
Pulveris Jacobi gr. iij;  
Extracti hyoscyami gr. iij.

Fiant pilulæ ij, h. s. sumendæ.

"From this time the disease rapidly abated, and having discontinued his applications to me, he became fat, got into health, and is now in Germany.

"The chief feature in the treatment of this case is the combination of the tincture of opium with the diluted acid, and the external application of the hydrocyanic acid, in the form of ointment. The opium thus combined seemed to allay the irritation, and certainly augmented the tonic power of the bark; whilst the ointment deadened the insupportable itching which had caused the tearing of the skin."

eruption of prominent pustules, full of an opaque yellowish fluid, and surrounded by an areola of the most vivid red. These were associated with solid papular elevations, slightly prominent and containing no fluid, between which the skin preserved its natural tint and appearance.

Accidental pustules of this kind may become excoriated. Vial mentions the case of a man who had his face made raw from having rubbed it with the juice of the *euphorbia cyparissias*.

571. *Pustules from the application of certain inorganic substances.* The most remarkable of these pustules are such as follow the application of the tartrate of antimony to the skin, either alone, or mixed with hog's lard. In so far as form and size are concerned the pustules produced by this means have some resemblance to those of variola and ecthyma.<sup>1</sup> Artificial eruptions of this kind are usefully excited in a great number of different diseases; of course it does not enter into the plan of this work to consider these under a therapeutical point of view; I only take the opportunity of stating that whooping-cough and chronic inflammation of the larynx are those complaints in which they have always appeared to me to be attended with the best effects.

These pustules, at their height, are flattened, and of the size of lentils. They contain a pseudo-membranous deposit and some purulent serum. They almost invariably present a small brown point in their centre. Their base is surrounded by an areolar blush two or three lines in diameter, which is lost insensibly in the natural hue of the skin, or blends with the areola of the neighbouring pustules when they are very close to each other.

On the few next days after their appearance they continue to enlarge; the fluid they contain becomes thicker and whiter; their central brown spots grow larger and acquire a darker hue. If the cuticle be removed with a view of examining the interior of these pustules, a sub-epidermic pseudo-membrane is found, deposited on the surface of the papillæ of the corion, which appear elongated, injected and often infiltrated with blood. The central crusts become larger and larger, the areolæ diminish, and the desiccation is completed before any long period elapses. On the following days the crusts are thrown off, leaving small violet-coloured marks and indelible cicatrices of a circular shape upon the skin.

The pustules are occasionally intermingled with others of smaller dimensions, of a semi-globular form and not depressed in the centre.

The pustules produced by the application of tartrate of antimony are formed with greater or less rapidity, according to the irritability of the skin and the quantity of the salt employed. They are larger and more painful when they follow the application of the pure tartar emetic to the skin by means of a Burgundy pitch plaster, than when it is incorporated with lard or spermaceti ointment. In elderly and weakly persons the pustules have usually a violet or livid tint; they are then ecchymosed, and contain a quantity of sanguinolent fluid; under these circumstances they bear a great resemblance to the pustules of ecthyma *cachecticum* and the bullæ of rupia. A woman thirty years of age entered the hôpital St. Antoine on account of a chronic peritonitis and an ulcerated state of the bowels, accompanied with profuse diarrhœa. I directed the surface of the abdomen to be rubbed with the ointment of the tartrate of antimony, which caused the eruption of a crop of large, violet-coloured, sanguinolent pustules, some of which were as broad as the bullæ of rupia. The fluid they contained dried up into black and very adherent incrustations. This woman having died, I had an opportunity of examining the state of the skin upon which they were developed. I found it softened and perforated towards the centre of the different scabs.

I have oftener than once remarked pustular eruptions upon the genital organs of those patients who had been directed to rub the chest or abdomen with an ointment of the tartrate of antimony. Such eruptions have always appeared to me to be owing to a small quantity of the unguent having been inadvertently carried to these parts, the integuments of which being soft and moist, and abundantly supplied with follicles, may be supposed peculiarly susceptible of the action of this stimulant. These adventitious eruptions, however, have been

<sup>1</sup> Jenner. On the influence of artificial eruptions in certain diseases, 4to. Lond. 1807. Lombard. Note sur l'éruption du tartre stibié à l'extérieure. (Gaz. Médic., 1833, p. 246.)

attributed by some observers to a secondary effect of the tartrate of antimony absorbed into the system.<sup>1</sup>

572. *Pustular eruptions produced by arsenic.* Girdlestone informs us that he has seen eruptions of the skin succeed the use of arsenical preparations. The following is a new instance of this kind. Joseph Hubert, two days after having pounded a large quantity of arsenious acid, was attacked with an eruption which was already of eight days standing when he entered the hôpital de la Charité. The whole of the face was covered with crusts of a yellowish-green, some of them isolated, others confluent, under which the skin looked red. In the spaces between the crusts, small psudracious pustules were perceived here and there, analogous to those of impetigo; the eyes were watery and slightly inflamed; the features were still swelled, but less so than they had been on the second day of the eruption. Some small clusters of pustules and similar crusts were disseminated over the hands, arms, scrotum and root of the penis. None were discovered on the hairy scalp or trunk. The patient had no fever; the tongue was white, the abdomen not particularly sensible. He was bled from the arm, and the use of whey and of a bland diet speedily restored him to health.

#### IV.—FURUNCULI; FURUNCULAR INFLAMMATIONS.

Vocab. *Furunculi.*

573. The cells of the corion are penetrated at all points by small conical prolongations, derived from the subcutaneous cellular membrane. These everywhere accompany the vessels and nerves which proceed from the inner aspect of the skin towards its superficies, there to form the papillæ and vascular rete. Inflammation of one of these prolongations gives rise to the diseases entitled hordeolum or sty, and furunculus or boil; the simultaneous and confluent inflammation of several of these appendices constitutes anthrax or carbuncle.

574. The proper cutaneous tissue constantly participating to a greater or less amount in the inflammation of these processes of the cellular substance, I have felt called upon to devote a particular chapter to the consideration of the furuncular inflammations. They are three in number: sty, boil, and carbuncle, and approximate so closely in their causes, seat, progress, and termination, that they may be regarded as mere varieties of one and the same form of inflammation. Left to themselves, these affections always terminate in the mortification and subsequent expulsion of one or more of the small cellular cones of the dermal tissue, which are then designated by the title of *cores*. This peculiar termination of furuncular inflammation is generally ascribed to the resistance offered by the fibrous corion to the expansion of the cone of inflamed cellular membrane, which consequently undergoes a kind of strangulation, and perishes.

575. The occurrence of furuncular inflammation is frequently connected with the existence of a disordered condition of the stomach and bowels; this form of disease is scarcely ever the effect of mere irritation applied immediately to the skin.<sup>2</sup>

576. The three affections composing this group are distinct from the other phlegmasiæ of the skin in their seat, which is in the cellular substance of the reticulated texture of the corion. They differ from the gangrenous inflammations properly so called, inasmuch as they do not appear under the influence of any *specific* cause, and in the circumstance of the sloughing that does occur, being attributable, in great measure, to the anatomical structure of the parts affected. Furuncular inflammations consequently present a particular curative indication, namely: to relieve the strangulation of the cellular appendices that penetrate the reticular texture of the corion.

577. Hordeolum and furuncle are two diseases of such common occurrence, so universally known, and generally so unimportant, that I

have deemed it needless to give the details of any particular case of either of them.

FURUNCULUS. BOIL.

Vocab. *Boil, Furuncle.*

578. Furuncle is an inflammatory swelling of the skin and cellular substance, of no great size, circumscribed, conical and prominent, hard, very red, hot and painful, and terminating in the formation of a very small quantity of matter and the expulsion of a mass of mortified cellular membrane, known under the name of a *core*.

Furuncles are observed to occur most frequently on the buttocks, thighs, arm-pits, the back, nape of the neck, and anterior parts of the abdomen.

579. *Symptoms.*—The disease begins by a small hard and conical tumour of a vivid, or violet-red colour, which, although probably not larger than a pea when first discovered, may, within a few days, attain the size of a large walnut. The pain which accompanies the development of a boil, has been compared with some justice, to that which would follow the passage of a drill or gimblet through the skin. From the fourth to the eighth day, the boil rises in a point; its apex becomes white, then softens, and finally gives way, when a small quantity of sanguinolent pus escapes, and the top of the sloughy substance is exposed. This opening in the skin is commonly as minute as if it had been made with a fine probe; even in furuncles of the largest size it scarcely exceeds a line in diameter, although the slough beneath is frequently several lines in breadth and thickness. This slough or core, formed of a small piece of the cellular membrane infiltrated with pus, is thrown out between the tenth and twelfth day. After its expulsion, whether this have been spontaneous, or accomplished by means of pressure, the tumour seems pierced from its apex to its base, by an open-mouthed cylindrical cavity. The pain now ceases, the swelling disappears, the skin collapses, the cavity left by the core fills up, and after the cure, which is accomplished between the twelfth and fifteenth day, no trace of the disease is left, save a small depressed cicatrice of an irregular round shape and a dusky red colour.

Between the common furuncle, the summit of which exhibits one small opening only, and well-marked and sloughing anthrax, there is a disease of an intermediate description, in which the apex of the tumour is pierced with a number of small orifices that ultimately unite and compose a single opening of an irregular circular shape and considerable magnitude. This affection has by several pathologists been denominated furunculus *anthracoides*.

The development of one furuncle is frequently followed by the appearance of several others, each of which pursues its course uninfluenced by those in its vicinity. The size of these is various; one in particular is usually much larger than any of the others.

580. Furuncles are not commonly attended with fever, unless the individual boils be extremely large, or their number very great. When they appear on the perineum, between the anus and scrotum, the urine is generally passed with pain and difficulty. When they occur on the nucha, shoulders, or buttocks, they frequently occasion acute inflammation of the lymphatic vessels and glands of the neck, axillæ, and groins.

581. *Causes.*—Frictions performed with irritating ointments, want or due attention to cleanliness, the use of sulphureous, mercurial, alkaline, and other baths; several inflammatory affections of the skin, such as small-pox, and ecthyma; the application of blisters, and the deeper inflammation produced by a seton, &c., may occasionally be observed causing the production of boils. They seem also at times to appear simultaneously with slight chronic inflammatory affections of the digestive organs; but they also very frequently occur without any appreciable cause, and particularly at the termination of other diseases.

582. *Diagnosis.*—Furuncle does not differ from Hordeolum save in the circumstances of size and situation; hordeolum being always of inconsiderable dimensions, and situated on the edge of the eyelid. The small boils of the penis and prepuce are exactly similar to sty in the circumstances of form and size. Anthrax in fact is itself no more

<sup>1</sup> Gazette Med., 1832, p. 842.

<sup>2</sup> Yet the application of blisters, &c., is frequently followed by the subsequent development of boils in the situations they occupied. Vide § 581.—R. W.

than an agglomeration of confluent furuncles: the inflammation has then attacked a surface of some extent, and a mass of the cellular prolongations have been at once stricken with sphacelus. The small abscesses occasionally observed in the skin after the absorption of purulent matter, differ from furuncles in their progress, their flattened form, and the absence of a sloughy core. (Case XCIII.)

583. *Prognosis*.—Furuncle is by no means a serious disease; it is one indeed which frequently appears to form a crisis in other acute and chronic affections. It occasionally happens, however, that among the aged, and individuals of a bad habit of body, repeated eruptions of boils are observed to take place whilst the constitution is gradually giving way.

584. *Treatment*.—It has been said that furuncles might be arrested in their progress by cauterizing them with the lapis infernalis. The operation is by no means very painful, but the truth is, it seldom proves effectual; and as patients generally prefer such palliative measures as bathing the part affected with tepid fomentations, and the application of emollients and narcotics, we are generally content with endeavouring to prevent any fresh eruptions, leaving such as already exist to pursue their course, for it very rarely happens that boils are of such a size or so severely inflamed as to require the local abstraction of blood, or the division of the skin. When one or more of these tumours prove very painful, however, the simple division of the integument is the most speedy and efficacious measure in bringing relief that can be adopted. A bread and milk or linseed-meal poultice is the best, as it is the topical application most frequently employed in the treatment of boils. When one crop of boils appears repeatedly after another, the morbid disposition which engenders them is frequently checked by the exhibition of an emetic, or a few doses of slightly purgative medicine for several days successively. Yet it sometimes happens that these means prove unavailing, and it is only after effecting a modification in the constitution by appropriate regimen, and perseverance in a course of medicine for several months, that we succeed in putting a stop to these eruptions.

Fosbroke recommended large doses of the diluted sulphuric acid, in a proper vehicle, as a very effectual means of subduing the pain of boils already existing, and of preventing the appearance of fresh eruptions. He carried the dose of this medicine the length of six drachms daily.

#### *Historical Notices and particular Cases.*

585. Celsus<sup>1</sup> has left us a very good account of furuncle. Bichat<sup>2</sup> made a particular study of its structure. Fosbroke<sup>3</sup> and M. Daynac<sup>4</sup> have severally published observations on the disease. M. Guersent,<sup>5</sup> under the name of *furuncle atonique*, appears to me to have described a variety of ecthyma.

The following case of a number of abscesses appearing in the substance of the skin in consequence of the absorption of purulent matter, seems well calculated to display the characters which distinguish this rare form of disease from furuncle.

CASE XCIII.—*Abscesses in different parts of the body and in the substance of the skin, appearing in the form of an eruption.* Morize, aged forty, entered La Charité on the 9th of November, 1832. All that could be learned from the patient amounted to this, that he had been ill for a few days only, and that he felt pain in the right arm and elbow. His expression of countenance was evidently altered, but nothing much amiss was discovered after a careful examination. The pulse was not rapid, and the state of the digestive organs and thoracic viscera seemed satisfactory. The patient consequently attracted little attention for several days—he was held to be affected with articular rheumatism of no great severity. Unexpectedly however, an abscess the size of a small walnut was discovered below the elbow joint. It was not very painful, and not being opened it shrank and disappeared spontaneously a few days afterwards. The pulse at this time was frequent, the tongue moist, the cast of countenance morbid. The

patient complained of general uneasiness and of wandering pains in the limbs. His state was now deemed alarming, although this did not appear to depend on any particular affection of the viscera contained in the great cavities. Four days before his death, Morize sank into a state of prostration; the pulse became small and rapid, the tongue hot, dry, &c.; at the same time a number of small spots resting on a hard basis appeared upon different parts of the surface. Two days before his death, an abscess was discovered in the region over each cheek bone, the skin of which had previously been red, swelled and inflamed. At the same time there appeared upon the neck and upper parts of the chest, a multitude of small tumours the size of a pea or a little larger; the bases of these were in general hard, their summits soft; but several of them were uniformly softened throughout. The patient got worse and worse, and at length died in a state of low delirium. On examining the body after death, the following appearances were discovered.

*Externally*.—An abscess over each cheek bone as large as a walnut, containing a quantity of reddish-gray pus. On the neck several tumours the size of a pigeon's egg. Nothing was discovered when the muscles were cut into. The thighs and legs were beset, in the same way as the parts already mentioned, with small cutaneous and larger subcutaneous abscesses. An incision carried through the muscles of the leg laid open an enormous abscess, which seemed to have destroyed the whole of the tibialis anticus, and denuded the bone in its vicinity. Another abscess of somewhat smaller size was discovered in the same situation in the left leg. Three others, the size of large walnuts, were detected in the substance of the gastrocnemii muscles.

*Articulations*.—Both of the shoulder, elbow, and wrist, hip, knee, and ankle joints, contained a considerable quantity of yellowish or rather greenish fluid, thicker than the proper synovia, and more like mucous than serum.

The brain was healthy. The left lung was covered with a thin layer of a recent pseudo-membranous deposit. The substance of the lung was loaded posteriorly; in other parts it was perfectly crepitating. In the lower part of the superior lobe of the right lung there was found an abscess as large as a hazel-nut. The heart was healthy, as were the large vessels of the thorax and abdomen. The abdominal viscera, except the spleen,<sup>6</sup> which was very soft, were natural.

586. There is the greatest analogy between this case and two others, which will be found embodied in the memoir of Dance on phlebitis.<sup>6</sup>

#### HORDEOLUM.

##### *Vocab. Hordeolum, Sty.*

587. Hordeolum or sty is a small furuncular tumour of the eyelids, observed most frequently near the free edge of the upper lid, and the greater angle of the eye.

588. *Symptoms*.—Sty may occur as an acute or as a chronic complaint. In the former case it appears in the shape of a tumour, the size of a barley-corn, oblong, rounded, prominent, of a deep-red colour, and tipped on its apex with a small yellow speck of suppuration. This small tumour, which is attended with acute pain and considerable swelling of the eyelids, bursts and discharges a little clear and serous pus. The opening of the skin soon closes, and a second white point makes its appearance upon the tumour, which ultimately giving way, permits a sloughy core to escape with the effect of immediately putting an end to the whole of the morbid symptoms.

The second variety of sty consists of a small hard, red, and indolent tumour, which, after having remained stationary for several weeks, is at length attacked with inflammation of a more active description, when it terminates in the same manner as the variety previously described.

589. Whatever the course of hordeolum, it still presents two very marked and apparent peculiarities. The tumour at one time projects more exteriorly than towards the eyeball, in which case it impedes the vision but little, and the skin is free to give way and suffer the

<sup>1</sup> Celsus. De re medica, p. 236, lib. v. sect. xxviii. Ed. Fournier et Ratier.

<sup>3</sup> Edinb. Med. and Surg. Journ., v. xviii. p. 64.

<sup>4</sup> Revue médicale, Septembre 1829, p. 416.

<sup>5</sup> Archives génér. de méd., t. i. p. 336.

<sup>6</sup> Arch. gén. de méd., t. xviii.

core to escape. At another time, however, the sty, projecting on the inner surface of the eyelid, irritates the ball of the eye by its constant friction upon the conjunctiva. In this case the mucous membrane of the eyelid becomes softened, and is finally perforated over the most prominent point of the tumour.

590. *Causes.*—The occurrence of hordeolum is frequently observed to coincide with a deranged condition of the digestive functions. This furuncular inflammation consequently is very commonly observed among individuals addicted to the pleasures of the table or to spirituous potations. The disease appears occasionally with something like the regularity of a periodical distemper. Females have also been known to be troubled with it for several months before the appearance of the catamenia, and to suffer repeatedly at each recurrence of this evacuation.

591. *Diagnosis and prognosis.*—Hordeolum differs from the rest of the furuncular inflammations in its seat, its small size, and the slightness of the general and local symptoms that attend it.

592. *Treatment.*—An attempt may be made to cut short the progress of sty by applying pounded ice to the eyelid from the moment the disease is discovered; few, however, will be found ready to submit to this application, which, moreover, has not been known to succeed completely in any one instance in which it has been used. When the sty is very much inflamed a small cataplasm of roasted apple or crumb of bread, applied between the folds of a fine muslin rag, relieves the pain, and seems to hasten the expulsion of the core, a consummation which, when it is long looked for in vain, is occasionally brought about by the aid of a slight degree of pressure to the base of the tumour. When hordeolum occurs in an individual of scrofulous constitution, Weller advises the application of cataplasms of hemlock and saponaria, with the addition of camphor, to prevent the occurrence of the small induration which is one of the frequent consequences of this complaint.

As in furuncle, relapses are frequent in hordeolum. The only mode of preventing these is to attack, by appropriate regimen and medicinal means, those constitutional causes which appear to have an influence on the development of the disease. (a)

#### *Historical Notices.*

593. Celsus<sup>1</sup> has pointed out hordeolum very distinctly. Scarpa<sup>2</sup> and Weller<sup>3</sup> have given good accounts of its characters and mode of treatment.

#### ANTHRAX.

*Vocab. Anthrax, Carbuncle.*

594. Anthrax is an acute inflammation simultaneously affecting several of the contiguous cellular cones that penetrate the reticulations of the true skin. It appears in the form of a circumscribed very hard and very painful tumour of a deep red colour, accompanied with a sensation of burning heat, and is invariably terminated by the mortification of a mass of the cellular substance and the destruction of the corresponding portion of integument.

595. *Symptoms.*—Anthrax is most commonly developed on the nape of the neck, the back and shoulders, the parietes of the abdomen and thorax, and on the buttocks and thighs. The disease often begins in the shape of a small tumour but a few lines in diameter, and

(a) When suppuration has taken place, the sty may be punctured with a lancet. Scarification with the shoulder of this instrument and rubbing the part with mercurial ointment, have, within my own experience, caused a resolution of the inflammation, and thus abbreviated the disease. In scrofulous subjects, touching the parts with lunar caustic will hasten the cure after suppuration, and act in a degree also as a preventive.

<sup>1</sup> De re med., lib. vii. cap. 7.

<sup>2</sup> Delle princ. Malattie degli occhi, 8vo. Ed. 5ta. Pav., 1816. Transl. by J. Briggs, 8vo. Lond., 1806.

<sup>3</sup> Weller. Krank. d. Mensch. Auges. 3te. Aufl., 8vo. Berl., 1826. Transl. by Monteath, 2 vols. 8vo. Glasg., 1821.

very similar to a common boil, save when its apex is covered, as occasionally happens, with a sanguinolent bleb. Anthrax, however, is sometimes seen, even from its very commencement, of much larger dimensions, in which case it advances with such rapidity, as in eight or ten days to have acquired a diameter of as many inches. In the same measure as anthrax spreads, it becomes more prominent and penetrates more deeply. It continues extremely hard through its whole extent up to the period at which the cellular tissue is attacked with mortification. After this, the circumference still remains very firm, and the base continues to spread, whilst an obscure fluctuation may be discovered in the centre of the tumour. The violet tint of the skin does not disappear with pressure; the heat, which is sharp and scalding at first, especially about the centre of the tumour, does not decline until after the formation of one or more openings; finally, the pain, alternately gravative and tensive, extends to the circumference of the indurated base.

When anthrax is left to itself the skin which covers the tumour acquires a violet or bluish tint, and after the lapse of some days, having become thin and softened, it gives way in several places, when a small quantity of bloody pus, mingled with shreds of mortified cellular membrane, is discharged. It may also be stricken with death over some considerable extent, and present the black colour and insensibility characteristic of sphacelus. On the succeeding days the inflamed skin is successively softened in various other points, and new perforations take place, from the bottoms of which whitish sloughs of cellular membrane may be extracted. The modified cellular substance never assumes the black colour of the gangrenous skin. The perforations enlarge, either from the destruction of the integuments in their circumference, or by becoming united together. They all continue to pour out a little thick pus which is rendered sanguinolent, apparently by the accidental rupture of some minute artery or vein. When the perforation in the integument is considerable, the sloughy cellular substance exhales a fetid odour, which however is very different from that usually disseminated by animal substances in a state of putrefaction. By slow degrees the sloughs are detached, the discharge becomes more abundant and less thick, and the pain, heat, and tension diminish. After the detachment of the mortified parts the superficial fasciæ are occasionally found perforated, denuded or eroded; the integuments in the circumference of the anthrax are loosened, thinner than natural, of a bluish colour, and in some places so much disorganized as to be incapable of reuniting with the subjacent tissues.

If the disease terminates favourably, a cicatrice is formed in part from the ulcerated surface, and in part by the reunion of the loose flaps of skin. This cicatrice is always irregular, puckered and depressed, and long retains a dusky-red or brownish hue. It is occasionally intersected with thick bands which occasion considerable deformity and render certain motions difficult.

596. Anthrax often makes its appearance without having been preceded by any evident disorder of the principal functions. Patients, however, do occasionally complain for a few days before its development of anorexia, lassitude, chills or shivering fits, and other symptoms usually observed on the invasion of acute diseases. When the tumour is voluminous it is very regularly attended with febrile symptoms of greater or less intensity; there are restlessness and want of sleep; the skin is dry, the urine high coloured and scanty, the belly is bound, and the head is heavy and painful.

597. These general symptoms attendant upon anthrax may be complicated with various others according to the regions of the body upon which the disease occurs:

1st. When it is developed on the lateral or fore parts of the neck patients complain of dyspnœa, cough, and sense of heat in the larynx and trachea; the face is also flushed, and there is headache of the most violent description.

2d. When the parietes of the thorax are the seat of the disease the inflammation may be repeated, as it is said, in the pleura or lungs, and occasion pulmonary symptoms of various degrees of severity.

3d. Lastly. Anthrax attacking the parietes of the abdomen is occasionally greatly increased in severity by the sudden occurrence of peritoneal inflammation.

598. Various forms of cutaneous inflammation may appear along with and complicate anthrax. Furuncle, of all these complications,

is undoubtedly the most common. Boils, indeed, very generally precede the attack of anthrax; they, however, even more constantly succeed the disease, appearing in crops around the circumference of the tumour.

599. *Causes*.—Children and the youthful are much more rarely affected with anthrax than adults and the aged. The disease is frequently seen attacking females about the critical period of their lives. It may arise from the application of acrid and irritating substances to the skin, the bites of insects, or filthiness. It occurs still more commonly as one of the sequelæ of measles, small-pox, and several other diseases of the skin. Like erysipelas, anthrax has also been seen as a consequence of the prolonged influence of certain causes which appear to act primarily on the digestive organs.

Anthrax is more frequent in the spring time and summer than in autumn and winter.

600. *Diagnosis*.—Anthrax is easily distinguished from the other furuncular diseases. Boils present but a single opening, and are smaller in size and more conical in shape than anthrax; they also commonly occur in succession, several following one after another. Anthrax, on the contrary, from the time it is perceived, presents a flatter, less pointed and broader tumour than furuncle, and at a later period is perforated with several openings on its surface. The differences that exist between these two diseases must not, however, be made greater than they actually are; anthrax being in fact no more than a tumour formed by the agglomeration or confluence of several furuncles, a fact which was first demonstrated by Baron Dupuytren, and made generally known by the publication of his lectures on clinical surgery.

At a time when pathological anatomy had not yet made us familiar with the structure and true nature of anthrax, the disease was often confounded with another affection, the anthracion or malignant pustule, which has frequently been described under the same name. The anthracion, however, belongs to another order of diseases, and I shall by and by have occasion to speak of its distinguishing characters.

601. *Prognosis*.—When anthrax is of moderate size and the individual attacked appears otherwise of a sound constitution, it is unattended with danger. But the disease may have the most unfavourable issue when it is of large dimensions and is situated on the parietes of the thorax or abdomen, the viscera or lining membrane of which may be attacked with fatal inflammation.

The prognosis generally is unfavourable in the aged, in whom a considerable extent of the skin is frequently observed to become gangrenous.

602. *Treatment*.—To whatever cause anthrax may be traced, it is necessary to attack the disease in the very beginning, by blood-letting, proportioned in amount to the age and habit of the individual, and to the intensity and extent of the inflammation. A number of leeches ought also to be applied around the circumference of the swelling, and the bleeding from the bites of these encouraged by some emollient tepid fomentation, or the application of cupping-glasses. These measures may require to be repeated oftener than once.

Compresses dipped in the *coldest water* applied to anthrax, and frequently renewed, will be found singularly efficacious in allaying the pain. This application is much better than any form of warm cataplasm or emollient fomentation, which rather increase or keep up than allay pain by augmenting the morbid heat of the skin.

After the due employment of blood-letting and cold applications, the best means of putting an end to the inflammation and relieving the tension of the skin, at our command, consists in making a simple crucial incision through the centre, completely across and to the bottom of the swelling. This will generally be found sufficient in the smaller-sized carbuncles; but those of larger dimensions may require a much greater number of incisions to set every part of the tumour free. These incisions give immediate relief from the strangulation under which the parts involved in the swelling suffer, and the blood that is lost lessens the inflammation and prevents the threatened gangrene of the skin and processes of cellular substance that penetrate it, from taking place. The incisions, further, facilitate the discharge of purulent matter, and the escape of the mortified masses of cellular membrane; they also give prompt relief to the local pain, as well as

to the general phenomena thereby induced; to conclude, they abbreviate most materially the natural duration of the disease.

In dressing the part subsequently, the flaps must be gently compressed every day, so as to squeeze out the matter that may be formed and the shreds of cellular substance that may have become loose; the immediate surface of the wound may be covered with a piece of soft lint or linen rag spread with some mild cerate, and the whole enveloped in an emollient cataplasm. When the ulcer tends to cicatrization it is occasionally found necessary to remove the loose flaps of integument which have suffered too much to be brought to re-unite with the subjacent cellular membrane; attention must also be paid to keep the cicatrice as smooth and regular as possible.

603. At the commencement and during the progress of anthrax patients ought to be restricted to the regimen observed in acute diseases. When the tongue is yellow or white, and a bitter taste is complained of in the mouth, with but little thirst, many have advised the exhibition of a purgative or an emetic. I have not myself had recourse to either of these remedies in any case of anthrax I have encountered. I have always seen the functional disorders of the digestive organs, on account of which they have been recommended, disappear of themselves in the same ratio as the inflammatory affection of the skin drew towards a close. And yet the unquestionable utility of these remedies in cases of furuncular eruption might induce us to give them a trial under certain circumstances.

It seems almost unnecessary to add that the diseases which may accidentally complicate anthrax, such as peritonitis, pleurisy, &c., themselves require peculiar treatment, which indeed must be so much the more active, as their association with an acute inflammation of the skin commonly renders their progress more rapid.

When the disease has come to an end, a few sulphureous baths are almost always of service, especially to the aged.(a)

(a) In some cases of anthrax, of considerable severity, too, I have found a simple incision made down to the healthy tissue at the base of the tumour, suffice. Dressing with ointment of chloride of lime is good. After an emetic or purging, quinine and nutritive stimulants are often indicated, and, in place of opium, hyoscyamus or conium and camphor are preferred, when the first mentioned remedy disagrees with the patient. The following is a judicious summary of the treatment of anthrax.

“Free and early incision is to be made, usually of the crucial form, throughout the whole extent of the diseased mass; this evacuates the purulent formation, affords an exit for the sloughs when loose, and limits infiltration. But this is not enough. Potassa fusa follows the bistoury, and is used freely; by it the dying parts are at once converted into a dead eschar, healthy separation is accelerated, and injury of the system from absorption of the deleterious products of humid putrescence is almost at once arrested; and, further to insure fulfilment of the last indication, the slough, as it loosens, is to be carefully removed by knife or scissors. The practice seems severe, but no other will prove in all respects successful; and the more advanced the case, the greater the necessity for its adoption. Less pain is occasioned than might be supposed, the greater part of the cauterized tissues being already in a gangrenous state. Poultice is applied till the slough is discharged; then water-dressing, early medicated to meet approaching debility.

“The constitutional treatment is never thoroughly antiphlogistic. At the commencement, evacuations are necessary; for the stomach and bowels an emetic and purgation; for the liver, mercury, cautiously administered; then occasional alteratives, as perhaps the hydrargyrum c. cretâ. Early tonics and stimuli are required—bark, wine, ammonia, brandy, turpentine enemata, according to the features and exigencies of the case. So long as the power of swallowing remains, the remedies are to be perseveringly administered; for, provided the suitable local treatment has been practised, patients often rally successfully, even though previously in *extremis*. Omit the use of the bistoury and potass—and all constitutional care, however skilful and unwearyed, will not arrest the tendency to collapse, or avert a fatal issue.

“These strong expressions, in favour of strong remedies, are of course applicable only to the more serious and urgent cases. There

*Historical Notices and particular Cases.*

604. The word ἀνθράξ in the Hippocratic writings does not appear to have a very determinate meaning, inasmuch as some commentators have held it applicable to *carbuncle* and others to *variola*.<sup>1</sup> The description of the ὑμή<sup>2</sup> of Celsus seems much more applicable to *furuncular anthrax* than that which he has given of the disease he entitles *carbunculus*.

Furuncular anthrax or carbuncle, the disease we are now discussing, and malignant pustules or anthracion, were long considered in France as varieties of the same disease. Baron Dupuytren was the first who drew the precise line of distinction between them, and who demonstrated the analogy of the variety of anthrax entitled *benign* to the common furuncle. This fact has been well authenticated by M. Cadet.<sup>3</sup> He gives three cases of anthrax evolved on the nucha and shoulders. I am myself possessed of the details of several; from among them I select one in which the disease occurred on the parietes of the abdomen, and which I attended along with M. Adelon. Among other remarkable peculiarities, the summit of the tumour in this case was covered from its first appearance with a broad, flat, sanguineous vesicle, the presence of which might have caused it to be regarded for a moment as a malignant pustule.

CASE XCIV.—*Anthrax*.—Baron M\*\*\*, almost fifty-five years of age, of a bilious and plethoric temperament, and subject to gout, summoned me on the 12th of October, 1822, on account of an inflammatory swelling which had made its appearance, without known causes, on the left hypogastric region. This swelling had been evolved three days previously in the shape of a small, hard, deeply seated pimple, highly inflamed, extremely painful, and having the look of a common boil. A broad, flat, bloody vesicle had formed on the surface of this small tumour on the second day after its appearance. This circumstance having excited fears lest the case should prove one of malignant pustule, a grain of caustic potash had been applied to the inflamed part.

When summoned, I remarked the following particulars: a flattened oblong tumour, of a deep red colour, hard to the touch, very hot and very painful, nearly three inches in its transverse diameter, and an inch and a half from above downwards across its middle, occupied the anterior and inferior part of the abdomen. A small eschar six lines in diameter appeared on its middle, which had been produced by the application of caustic. The disease appeared to be of a purely local nature, and was unaccompanied by any appreciable disorder of the chief functions of the body (*fifteen leeches applied circularly at the distance of an inch from the tumour; cool emollient cataplasms, and to promote the bleeding from the leech bites, a warm bath*). These measures only gave very momentary relief. During the following day and night the inflammation made rapid progress both in superficial extent and in depth. The pain became excessively severe; the redness of the skin, verging on a violet, spread transversely, and the tumour, next day less flat than heretofore, formed a longitudinal swelling, similar to that which is produced by pinching up a broad roll of the skin. The patient was now troubled with pains of the bowels and retching, the pulse had got full, and the belly was tense. I proposed and immediately performed the incision of the tumour. Its lengthened shape, however, induced me to confine myself to a single transverse cut, which passing through the entire thickness of the skin and subcutaneous cellular substance, was at least six inches in length, and extended from beyond the bounds of the inflammation, at either end, near the median line to the middle of the left flank. The incision was followed by the discharge of a considerable quantity of blackish blood, a marked diminution of the pain, and

are many examples of the disease, in which the swelling is but small, and constitutional disorder proportionally slight; in these simple incision suffices; in a day or two the slough is discharged, and granulation advances favourably.—*Miller's Principles of Surgery*, Am. edit., pp. 225–6.

relief of the abdominal symptoms, the occurrence of which had caused me serious alarm. (*Cool emollient poultices to the tumour; eau sucrée for drink; low diet.*)

The wound continued during four or five days from this time to discharge a quantity of purulent and bloody fluid. The oval formed by the anthrax began to contract from the third day after the operation, but the lips of the wound presented an appearance peculiar to this disease. On their edges a number of white points were distinguishable, formed evidently by the summits of the conical-shaped sloughy cores; several, indeed the greater number of these, could be laid hold of with the forceps, and taken away without pain; others still adhered by their deep extremities. These conical-shaped cores were of a yellowish-white colour, and pretty tough. On the eighth day after the operation the edges of the wound were irregularly indented, and presented numbers of small semicircular notches in the points which the cores had occupied. The wound was dressed regularly till the 2d of November, with a perforated pledget spread with cerate, compresses of lint, and an emollient cataplasm. A sloughy core made its way out at a point near the middle of the inferior half of the swelling. The ragged or toothed condition of the lips of the wound certainly retarded the cicatrization, which was nevertheless completed by the 18th of November.

Two small furuncles appeared: the one on the epigastric region, the other near the umbilicus. They both got speedily well spontaneously.

From this time to the 1st of August, 1826, Baron M\*\*\* had no attack of gout; neither did he suffer from certain fits of pain in the bladder, which used occasionally to alternate with the paroxysms of this disease.

## V.—GANGRENÆ. GANGRENOUS INFLAMMATIONS.

605. The distinguishing characters of the gangrenous diseases of the skin are their origin in a specific cause, and their rapid termination in gangrene.

The disease entitled Anthracion, Persian fire, and Malignant Pustule, may be taken as the type of this group, in which may be included pestilential bubo, typhoid gangrene, and the gangrenous affection of the cheeks and genital organs of children.

I shall here confine myself to a description of Anthracion, and indicate the features that distinguish it from the rest of the gangrenous affections.

## ANTHRACION.

Vocab. *Anthracion, Carbuncle, Malignant Pustule, Persian Fire.*

606. Anthracion appears in the shape of a large vesication or bleb, full of a sero-sanguinolent fluid; under this a small lenticular induration is formed, which is itself speedily surrounded by a phlegmono-erysipelatos areolar swelling, a larger or smaller portion of which is before long stricken with gangrene.

607. Enaux and Chaussier,<sup>1</sup> and a great many pathologists who have followed them, are of opinion that anthracion constantly follows inoculation, being produced by the contact of this gangrenous tumour, or of the offal of animals which have been affected by the disease. In support of this view they appeal to the following facts: 1st. Anthracion has been seen most frequently among smiths, veterinarians, shepherds, graziers, tawers, tanners, butchers, knackers, mattress-makers, &c., in a word, among individuals who have the care of animals, or who handle their carcasses and offal. 2d. Anthracion appears exclusively on such parts of the body as are habitually uncovered, such as the face, neck, hands, arms, &c., or upon others

<sup>1</sup> Enaux et Chaussier. Manière de traiter les morsures des animaux enragés, et de la vipère, suivie d'un précis sur la pustule maligne, 12mo, 1785.

which have been exposed accidentally. 3d. The disease has been more especially observed during epizooties with an eruption of bubos.

The same pathologists conceive that the sanguinolent serum poured out by the disease is one of the means by which it is propagated.

We are even informed that the blood of a sheep labouring under the disease having flowed over the back of a shepherd's hand, gave occasion to the development of anthracion, and that a butcher was attacked with the same formidable malady in the tongue, merely from having taken the knife, with which he was skinning an ox that had died of the disease, between his teeth for a few seconds. These statements are in perfect accordance with the results obtained by M. Leuret,<sup>1</sup> in his experiments on the changes undergone by the blood in different diseases.

Some would even persuade us, that the blood of an animal, not labouring under any gangrenous disease, but altered from other circumstances, may occasion anthracion when applied to the skin of man. In confirmation of this, the cases of two butchers of the Hôtel Royal des Invalides are quoted, who were attacked with anthracion from having killed and prepared the carcasses of a couple of oxen, overdriven, but in other respects perfectly healthy. The truth of this opinion, however, is extremely problematical.

Thomassin tells us that a woman, whilst engaged in dressing the gangrenous bubo of her husband, having touched her cheek with her fingers, soiled with some of the discharge from the sore, became affected within two hours with anthracion, in this situation, which spread with an alarming rapidity.<sup>2</sup> Hufeland speaks of a woman who caught the disease from having lain with another female labouring under anthracion. On the other hand, M. Jemina,<sup>3</sup> on the authority of his father, of different other practitioners, and of various experiments, communicated to Malacarne, (Brera. Giornale, vol. i., p. 460,) maintains that anthracion contracted from the contact of an animal affected with the disease, cannot be transmitted from one individual of the human species to another. In confirmation of this view I may state here, that one of my pupils, M. Bonet, of Poitiers, had the courage to inoculate himself with the matter of anthracion, without suffering any inconvenience from the operation.

It would appear, further, that anthracion is occasionally evolved sporadically in the human subject. No one doubts that the nine cases of *gangrenous pustule* (pustule gangreneuse) detailed by M. Bayle<sup>4</sup> are instances of true *anthracion*; yet this very accurate observer informs us, "That almost the whole of these patients were certain of never having touched the remains of any animal which had died of malignant pustule (charbon), and that those who had lately eaten any animal food were certain of having partaken of no flesh that was suspected." M. Davy la Chevré<sup>5</sup> has given six cases of anthracion, and in none of them is there any mention made of the patient having contracted the malady from another individual, or from a diseased animal.

Anthracion is believed to be pretty common in several districts of France;—in Lorraine, Franche-Comté, and especially in Burgundy. The disease is rarely seen in Paris. I have, however, met with it among tanners, butchers, and, more frequently still, among workmen who manipulate leather, and mattress-makers. During the three years that I was attached to the Hôpital St. Antoine, I saw several cases which all came from the same manufactory, in which the business of cleansing and preparing hair, imported from Russia, was carried on.

608. *Symptoms*.—When anthracion is communicated by way of contagion, the interval that elapses between the time at which the infection was received and the appearance of the gangrenous spot of

the skin, varies from a few hours to five or six days. Making the gravity of the symptoms the basis of a division, the whole of the cases of anthracion that occur may be arranged under three heads: 1st, *slight anthracion*, with circumscribed mortification; 2d, *severe anthracion*, with diffused mortification; 3d, *fatal anthracion*, with alteration of the blood, and affection of one or several of the viscera.

609. 1st.—Anthracion with circumscribed mortification. The animal poison which produces anthracion is occasionally limited in its effects to the excitement of a trifling degree of inflammation which I have seen several times, and which M. Davy la Chevré has described under the title of *pustule maligne prominente*. It begins with a seropurulent elevation, the base of which, hard, tense and deeply-seated, is not long of being surrounded by a phlegmono-erysipelatous inflammation. The central point of the tumour is attacked with gangrene, but it rarely happens that the mortification extends beyond this its primary seat; the morbid process stops spontaneously, and almost at its outset. Case XCVI belongs to this variety.

610. 2d.—Anthracion with diffuse gangrene. This variety begins with a considerable degree of pruritus which is succeeded by the appearance of a red spot like a flea-bite. The vesicle, of the size of a millet-seed at first, soon acquires larger dimensions, and, if not ruptured by the patient, bursts spontaneously. Twenty-four or thirty-six hours after the attack, a small, hard, and circumscribed nucleus, having the form and size of a lentil, is perceptible under and around the seat of the vesicle; in the circumference of this a soft, but still resisting swelling, of a reddish or livid colour, covered by and by with secondary sero-sanguinolent vesicles, at first isolated, but speedily becoming confluent, is developed. The central point, now of a brownish hue, extremely hard and very insensible, becomes gangrenous. The inflammation extends to a considerable distance; the neighbouring skin is red and shining; the subcutaneous cellular tissue is puffy, tense, and to appearance emphysematous. The diseased part is numb, without proper sensation, and the gangrene advances with rapidity.

If the disease ceases to make further progress, an inflamed circle of the most vivid red appears around the eschar; the tumefaction which had spread extensively diminishes at the same time, and the patient feels something like an agreeable warmth accompanied with a pulsatory motion of the part affected. The pulse revives; the strength increases; occasionally some degree of fever occurs which is speedily resolved by a gentle perspiration; suppuration sets in between the living and dead parts, and the detachment of the eschar leaves a suppurating surface of various extent in different cases.

Should the disease, on the contrary, tend to an unfavourable issue, general symptoms of great severity occur: the pulse is small and contracted; the patient complains of a feeling of anxiety; he is attacked with fainting fits; the tongue is dry and brown; the features are shrunk; the skin is parched; the eyes are glassy; the moral courage and physical strength are gone; cardialgia and low delirium precede the fatal termination.

The duration of the different stages of this variety of anthracion is uncertain; that of the incubation varies between one and two hours and several days; the second, characterized by the formation of the primary vesicle, extends to an interval of from twenty-four to thirty-six hours; the third, marked by the evolution of the central nucleus and the appearance of the areolar tumour, does not generally exceed a few hours; the fourth and last, announced by the occurrence of gangrene and other local and general symptoms of different degrees of severity, varies from one to several days according to the issue which the disease is to have.

611. 3d.—Anthracion with alteration of the state of the blood or affection of the viscera.—In this variety, the symptoms advance with frightful rapidity; death occasionally intervenes within the first eighteen or twenty-four hours from the invasion of the disease. The alteration of the skin is occasionally of no great amount; and the fatal termination and the formidable symptoms that precede the catastrophe are only explicable on the supposition of some change having taken place in the state of the blood, or the occurrence of gangrene in some of the principal viscera. (Vide Cases XCVI and XCVII.)

612. Anthracion, further, is not without its varieties according to the regions of the skin upon which it is developed.

<sup>4</sup> Bayle (G. L.). Considérations sur la nosologie, la médecine d'observation et la médecine pratique, suivies d'observations pour servir à l'histoire des pustules malignes, 8vo. Paris, 1802.

<sup>5</sup> Davy la Chevré. Diss. sur la pustule maligne, 4to. Paris, 1807.—I ought to add here that in a great number of cases evidently belonging to anthracion in their symptoms, it has been impossible here to trace the disease as having been transmitted by contagion. See the case of M. Liétré, quoted lower down, and that of M. Carrel, (sur une gangrène de la lèvre attaquée infructueusement par le feu et suivie de mort). Recueil de la société de Santé de Lyon, 8vo. 1798, p. 308, &c.

1st.—*Anthracion of the face* is not merely accompanied with a phlegmonous erysipelas of the features, but the puffing and inflammation occasionally extend to the neck and fore part of the chest. When the eyelids are the primary seat of the affection, it occasions an enormous and very painful tumefaction of the face, accompanied with intense headache or delirium, occasionally with the loss of the eye, always by the eversion of the eyelids, which are then frequently formed by the orbicularis muscle and the conjunctiva alone. When the upper eyelid is the only one implicated, the lower is often seen to be carried somewhat further up than usual, in consequence of the efforts made by the patient to preserve the eyeball from the action of the light; there is an abundant flow of tears; the transparent cornea inflames and speedily becomes opaque. To remedy the destruction of the eyelids consequent on this affection, it has been proposed to restore them by means of an operation on the same principles as those of the Rhinoplastic or Taliacotian process.

Wherever muscular fibres are contiguous to the skin, it is observed that there the gangrene extends less deeply. Nevertheless, when the lower lip is attacked with anthracion, this part is apt to be destroyed through a considerable extent, either by the disease or the action of the caustics employed with a view to arrest its progress. The deformity that results is attended with the constant and involuntary flow of the saliva.

2d. The development of anthracion on the neck is accompanied by a phlegmono-erysipelatos inflammation which impedes respiration and deglutition. Besides these, there are various other symptoms present, such as pytalism, nasal hemorrhage, swelling of the face, &c.

3d. Anthracion attacking the parietes of the thorax is always accompanied with inflammation of the subcutaneous cellular tissue of the thorax and axillæ.

4th. When the back of the hand or instep is the seat of the disease, every part of the limb is successively attacked with phlegmono-erysipelatos inflammation.

613. When anthracion becomes not merely a local but a general disease, unequivocal symptoms of an altered condition of the blood, of pulmonary (Cases XCVI and XCVII) or gastro-intestinal inflammation of an unfavourable description, or of the absorption of pus into the system, are observed.

In a case of gangrene of the lower lip, presenting all the symptoms of anthracion, M. Littré<sup>1</sup> found pus within the veins of the face, and a number of small abscesses in the substance of the lungs.

614. *Alterations of structure.*—Cases XCVI and XCVII will be found to illustrate not only the nature of the alterations induced by anthracion in the skin and cellular membrane, but several which occur in the state of the blood, and in the lungs and stomach, analogous to those which Chabert met with in the bodies of animals that had died of this disease (charbon). M. Virieul informs us that he found anthracion in the colon. M. Lambert<sup>2</sup> has given a good description of the gelatinous appearance of the serous deposits which are constantly found in the subcutaneous cellular substance, and occasionally in the cellular tissue of the mediastinum. A quantity of sanguinolent serum is very commonly found within the serous cavities in fatal cases of anthracion.

615. *Diagnosis.*—At its first appearance, and when it is still undistinguished by the hard and unequal elevation surmounted by a sanguinolent vesication, anthracion might be mistaken for the inflamed and painful induration produced by the bite of certain insects; these bites, however, may always be recognized by the presence of a minute central, and yellowish-coloured point.

Furuncle, at its commencement, shows no pustular or vesicular bleb on its summit, similar to that of anthracion, which, moreover, is speedily surrounded by a diffuse and emphysematous-looking inflammation, very different from any thing that is seen in furuncle.

When anthracion has acquired a very large size, and gangrene, to a greater or less extent, has taken place in a portion of integument, the disease can only be confounded with phlegmonous and gangrenous erysipelas, with the gangrenous affection of the cheeks and labia majora occasionally met with in children,<sup>3</sup> or with the bubo of

the plague. Phlegmonous erysipelas, however, is not preceded by a pustule or a sanguinolent vesicle in a particular point, and is not contagious; the disease, in fact, only ends in gangrene through excess of action; it is often treated successfully by blood-letting, a measure which is always prejudicial in anthracion.

Anthracion differs from the gangrenous affection in the cheeks of children in this: that the mortification in the latter malady begins on the inside of the mouth and only extends consecutively to the skin, and in the origin of the disease in this instance being altogether independent of contagion.

The local characters of anthracion bear the greatest similarity to those of the pestilential carbuncle; the latter, however, is preceded, and accompanied by the series of general and particular symptoms characteristic of the plague.

Several fruitless attempts have been made to distinguish anthracion from the malignant carbuncle of animals, especially from that which attacks sheep and other woolly cattle.<sup>4</sup> The disease in animals is, in effect, characterized by the occurrence of a very voluminous uncircumscribed tumour, which yields to pressure, crepitating like emphysema and exhaling a peculiar putrid odour. The centre of the swelling is black, as if burned or carbonized, its circumference is infiltrated with a brownish or yellowish-coloured fluid, and is distended with a very foetid gas; the substance of the heart is commonly found softened, and its external surface marked with spots of ecchymosis in the course of the blood-vessels; the blood contained in the heart and great vessels is generally fluid; in the veins it is very black, and occasionally in clots of a black or yellowish-white colour, the consistence of which is soft and gelatinous. The lungs, covered with small superficial ecchymoses, present here and there a number of black spots penetrating their substance deeply, and produced by a kind of local sanguineous infiltration. The inner coat of the stomach and intestines presents, in different places, blackish spots and prominences in the course of the vessels, formed by blood effused between the two inner coats, or under the peritoneal covering of these parts. The villous coat of the stomach is also occasionally found ecchymosed; the liver and spleen are gorged with blood; a degree of emphysema is often observed about the kidneys; no change is appreciable in the state of the nervous system. Now, in the anthracion of the human subject, the alterations that take place in the skin and subjacent cellular membrane are precisely the same as those discovered in the bodies of animals that die of malignant carbuncle. I have, further, had various opportunities of investigating extensive morbid changes in the organs of digestion and respiration, and in the condition of the blood, in the human subject, precisely similar to those which have just been described as occurring among animals. Lastly, the discharge that takes place from malignant carbuncle in the brute, applied to the skin of man, produces anthracion; the identity of these two affections consequently appears to me incontestable.

I shall by and by take occasion to speak of the analogy that subsists between anthracion and the Siberian carbuncle. (Vide Siberian carbuncle, in Vocab.)

616. *Prognosis.*—The first variety of anthracion, which is frequently described by writers, gets well spontaneously; the gangrene ends of itself. This happened in the case of a child, who was brought into the Hôpital de la Charité, in the year 1826, affected with anthracion of the upper eyelid.

The second variety is more serious; but its progress may very certainly be arrested by the use of caustics. The disease in the third variety is mortal, and may end fatally within twenty-four or thirty-six hours from the time of its appearance.

Whatever the form assumed by the disease, anthracion is always more serious when it attacks the head, neck, or eyelids, than when it appears on the extremities. It is very generally believed, also, that a very high or very low temperature aggravates the disease.

Anthracion occurring in women during pregnancy very commonly causes abortion.

617. *Treatment.*—As soon as the existence of anthracion is ascer-

<sup>1</sup> Journ. Hebdomad. Septembre, 1829, p. 449.

<sup>2</sup> Revue Médicale, 1830, p. 481.

<sup>3</sup> Baron. Mémoire sur une affection gangréneuse de la bouche, particulière aux

enfants (Bulletin de la faculté de médecine de Paris, 8vo. 1816.—Isnard. Essai sur une affection gangréneuse particulière aux enfants, 8vo. Paris, 1818.

<sup>4</sup> Huriel d'Arboval. Dictionnaire de médecine et de chirurgie vétérinaires, 8vo. Paris, 1826. Art. Charbon.

tained, the part affected must be deeply scarified and extensively cauterized. To be effectual, the incisions must implicate the whole of the mortified tissues, without, however, extending beyond the dead or dying parts. In the beginning of the disease the vesication must be opened, the fluid it contains absorbed with a little lint, and the denuded part covered with a dossil of a corresponding size, dipped in the liquid muriate of antimony, or with a small fragment of caustic potash, kept in its place by means of a strip of sticking plaster and a proper bandage. Five or six hours afterwards, this application must be taken away and the eschar covered with a piece of lint spread with the unguentum resinosum or some salve of a similar description. Next day, if it is found that no vesicular areola has been formed around the eschar, if the patient complains of but little pain, without smarting or pungent heat, we may conclude that the cautery has included the whole of the disease; if, on the contrary, a hard and deep-seated tumour has appeared around the primary seat of the disease, and symptoms of phlegmono-erysipelatous inflammation are present, the caustic must be applied again, taking the precaution first to remove the gangrenous parts, after dividing them by a crucial incision. This procedure is also proper when the slough which forms the centre of the swelling has already become hard and impermeable like a piece of dried hide; this must necessarily be removed to admit of the action of the caustic being expended on parts not yet sphacelated, after which they are to be covered with a tonic cataplasm.

The value of escharotics in the treatment of anthracion is incontestable. They are indicated so long as the gangrene shows a disposition to spread, or as its limits are not clearly defined. There are cases, however, in which these means, even when they have succeeded in checking the local disease, prove unavailing in warding off a fatal termination. When the *peculiar contagion* of anthracion has extended its influence to the blood, when it has caused a gangrenous affection of the stomach, or pneumonia of a bad character (Cases XCVI and XCVII), or otherwise, when pus has been absorbed into the system after the occurrence of gangrene, the disease is invariably fatal in its effects.

618. Acidulated diluents and wine mixed with an equal quantity of water are the remedies that are most commonly exhibited internally. The tartrate of antimony and purgatives have been recommended as calculated to subdue certain gastric symptoms. I have not myself had any opportunity of observing the effects of these medicaments in anthracion. They may possibly prove useful in the third variety of the disease against which merely local measures are always unavailing.

In several cases of the least serious kind of anthracion, and when there was no symptom of constitutional infection present, after having cauterized the part affected, I have used *compression* successfully as a means of removing the erysipelato-phlegmonous inflammation surrounding the gangrenous point.

I have also tried the local application of leeches in a case of prominent anthracion, without any serious ill effects, indeed, yet with such results as would prevent me from prescribing local blood-letting in any future case of the kind.

I have seen several cases of anthracion occurring on the forearm, which were attended with gangrene of such extent and depth as to require the amputation of the limb at a point above the diseased structures; the greater number of these cases terminated fatally.

The deformity and destruction of parts, consequent on the ravages of anthracion, frequently require surgical operations for their restoration. M. Lallemand<sup>1</sup> has given the details of the case of a little girl attacked with anthracion of the face in whom, by means of a very ingenious process, he succeeded in restoring the loss of substance which had happened in the under lip. (a)

(a) Closely akin to anthracion, if not one of its varieties, is gangrenous erysipelas, as described in pp. 66 and 67 of this volume, and the "Diffuse Cellular Inflammation" of English writers. Dissecting wounds and abscesses belonging to this order are especially apt to prove dangerous and fatal, if the subject examined had died of peritoneal inflammation. Mr. Nunneley describes the disease as a variety of erysipelas under the head of "cellular variety."

### Historical Notices and particular Cases.

619. Celsus describes anthracion under the name of *carbuncle*.<sup>2</sup> Guy

"The cellular variety, like that which equally involves both skin and cellular membrane, varies much in its violence, and owing, perhaps, to its being principally seated in the cellular membrane, which is the especial locality of true phlegmon, in mild cases, it presents us with a very near approach to circumscribed phlegmon. The mischief varies from little more than a whitlow, or a suppurating absorbent gland, to that form of the disease which induces a destruction spreading over almost half the subcutaneous cellular membrane of the body. So also does the rapidity of the disease differ much; in some cases it proves fatal in a few hours, in others not for many weeks, when the patient dies rather from the effects of the disorder than from the complaint itself.

"In the majority of cases the constitutional symptoms are preceded by some local affection, but not invariably, for at times the constitutional derangement appears without any local complaint, and the patient seems to be suffering under typhus fever, for which,<sup>3</sup> indeed, in more than one case, the disease has been mistaken; yet, even in these cases we may generally avoid the error, for in simple typhus the disorder only reaches its height after some time, but in this affection at a much earlier period, usually in a short time, as two or three days. There is intense local pain in the punctured part, if a puncture has been the exciting cause, with enormous diffuse swelling, and more or less redness.

"When the disease arises from venesection, the wound in the vein sometimes heals and remains so; at others, after having healed, it again opens; but more commonly it does not close at all, but remains open, the edges becoming thick, irritable and gaping, and there is a discharge of a thin, semi-purulent matter.<sup>4</sup> From this point the disease spreads as from a centre, though more towards the shoulder than towards the hand. Sometimes, although venesection may appear to have been the immediate exciting cause, the punctured vein is not found to have been implicated. In most cases, if the disease arises from the application of poison, as the bite of a serpent, or from a wound received in the examination of a body, there is a small vesicle or pustule which forms at the wounded spot, and which Dr. Colles appears to regard as possessing specific characters. However extensive the suppuration may be, there is seldom much in the immediate vicinity of the wound. In most cases the violence of the disease seems to be expended about the axilla and in the region of the pectoral muscles. The redness of the skin is not so conspicuous in this as in the preceding variety; it is, however, never altogether wanting; in all cases, at one period or another, the skin participates in the disease, sometimes very extensively. At times vesications occur, though not so frequently as in the cutaneous variety, which, indeed, we should not expect, inasmuch as they are the effect of the external surface of the dermis being inflamed. The large vesications which appear at a later period are more like the phlyctenæ preceding gangrene of the skin, which changes colour and undergoes precisely the same processes which were spoken of in the cellular-cutaneous variety. In one circumstance only does the gangrene in this variety differ from that which occurs in the former, namely, that the muscles are much more frequently affected. On account of the inflammation being deeper seated, it oftener passes beneath the fascia, when the muscles become soft, black, and completely disorganized. It is a matter of doubt if this arises from the muscular structure itself being inflamed, as Dr. Duncan supposed: to me it rather appears to result from the same circumstances as gangrene of the skin; in both cases the cellular matrix, in which the nutrient vessels and nerves pass to their distribution, is destroyed, and with it the vessels and nerves; as a necessary consequence the death of the part ensues."—Nunneley on *Erysipelas*, pp. 147–8, Am. edit.

<sup>3</sup> Duncan in Edinburgh Med. Chir. Trans., vol. i. p. 602. Dr. Colles in Dublin Hospital Reports, vol. iii. p. 209.

<sup>4</sup> In the milder forms of this disorder, which follow venesection, and which every practitioner must have often seen, this opening in the integuments serves as a vent through which the discharge takes place, when, after a few days of fever and irritation, the patient recovers.

<sup>1</sup> Archives génér. de médec., t. iv. p. 242.

de Chauillac<sup>1</sup> notices the principal features of the disease. Thomassin, Enaux and Chaussier have given us interesting remarks on anthracion generally. M. Costalat<sup>2</sup> has related the history of a case of the disease affecting the upper eyelid *without any surrounding erysipelatous areola*, but attended with alarming symptoms. M. Blandin<sup>3</sup> has published a case of anthracion *excited by contact with an animal affected with no gangrenous disease*, and cured by the application of the acidulous nitrate of mercury. M. Lisfranc<sup>4</sup> has made several remarks in favour of the actual cautery which he prefers to any form of potential caustic.

Anthracion has been seen complicated with œdema of the glottis;<sup>5</sup> additional observations on the disease and its complications may be found inserted in various periodical publications.<sup>6</sup>

CASE XCV.—*Circumscribed anthracion; cauterization; compression.* P. Monserant, Tawer, 26 years of age, and of good constitution, entered the Hôpital de la Charité, on the 12th of September, 1833. This man had been engaged in working among hides stripped from animals that had died of disease, when on the 4th of September, he perceived, without any premonitory symptoms, a small pointed spot surrounded with a red areola very like that which follows the bite of a gnat on the palmar aspect of the right forearm. Next day another small, very hard and non-vesicular spot made its appearance on the back of the hand of the same side. The first was so itchy that the patient soon tore it with scratching; the excoriation speedily became covered with a small black eschar, which two days afterwards was nearly two lines in diameter. Up to this period no constitutional affection had been perceived, but on the 7th, the arm began to swell, the axillary glands to grow painful, and febrile symptoms of considerable severity, attended with lassitude and pains in the back and limbs, set in, together with urgent thirst and a loss of appetite. Diluents, and emollient cataplasms seemed to relieve this state of affairs. The arm became less painful in the neighbourhood of the eschar which was surrounded by a circle of the cuticle detached by the effusion of a little purulent fluid beneath it.

When the patient gained admission into the hospital the constitutional symptoms had declined greatly. The right forearm presented an eschar five or six lines in diameter, depressed, dry, black, hard, surrounded by a very narrow red circle, which itself was circumscribed by a reddish areola covered with small epidermic squamæ. Although the distension of the skin was not considerable, the arm was still swollen, shining and red, especially on the dorsal aspect of the hand, and the forearm pitted on pressure. The patient made little complaint of pain, but rather of an unpleasant feeling of tension. The pulse was not increased in rapidity. After dividing the eschar, the part was touched with chloride of antimony, and the whole arm was firmly bandaged from the fingers to the axilla. The night between the 12th and 13th was good, and in the morning the patient was found almost entirely free from fever. The swelling of the arm had diminished, and the redness of the skin was succeeded by a yellowish tint, which gradually acquired a degree of intensity equal to what is observed after the resolution of an ecchymosis. Every thing went on favourably under the same plan of treatment: the slough becoming detached on the 18th, and the wound being healed over on the 30th of September, the patient was discharged.

CASE XCVI.—*Anthracion with gangrenous ulceration; death.* Ch. Chibot, a hair manufacturer, entered the Hôpital St. Antoine, on the 28th of May, 1829. This man had been out of health for some time. On the 23d he was so unwell that he could not go to his work. On the 26th the feeling of weakness and prostration increased; he was troubled with cough and retching. Nearly a month before his recep-

tion into the hospital he had had an eruption of itchy spots upon the elbow which became more troublesome than usual on the day he first felt seriously indisposed. According to the patient, weakness, prostration and spitting of blood are symptoms of frequent occurrence among the workers in hair. His daughter had died after an illness of five days with symptoms of this description, and one of his fellow-labourers had sunk some time previously, in two days. A young man 18 years of age, who worked along with the patient had been successfully treated for anthracion of the thigh in the Hôpital St. Antoine.

Chibot on the day of his entrance was extremely weak, and had fainting fits. The left lateral region of the neck is of a pale red, and slightly shining; there is a degree of puffiness on the same side, under the clavicle and towards the roots of the hair, where there is observed a gangrenous spot, the size of a split pea, which had been preceded by a pimple or spot, destroyed by the patient with his nails. A yellowish and not very consistent fluid, which stains the pillow, is poured out by the little ulcer, in the vicinity of which a number of small pustules, full of a somewhat turbid liquid, are perceived. The surface of the sore, when touched, causes no sensation of pain. A great degree of swelling extends over the whole of the left side of the neck, the ramus of the lower jaw, the shoulder, involving the clavicle and extending down both behind and before upon the chest. The touch conveys a feeling as if a quantity of fluid were effused into the cellular membrane under the skin, the sensation of œdema being in some places very distinct, whilst in others it seems as if a gaseous body were displaced by the fingers, as in emphysema. The base of the tongue is loaded with a yellow fur; the abdomen is slightly painful to pressure. The patient coughs at times; the thorax, generally sonorous, is however less so on the right than on the left side. The pulsations of the heart are weak. The patient complains of oppression, of a sense of sinking about the præcordia, as if the heart were compressed, and of wandering pains in the limbs. The pulse at the wrist is small and shrunk; the feeling of weakness is extreme, so that the patient cannot sit up, but sinks immediately like a lifeless mass, retaining the same position in which he happens to fall. The patient is haunted with the notion that he will not recover. (*Decoction of bark edulcorated.*)

At 4 o'clock the prostration had increased; I touched the whole surface of the sore with the red-hot iron. (*A tonic draught with bark and ether; weak wine and water.*)

30th.—The patient has had no sleep, but feels a little better; he is not so much sunk as yesterday, and the constriction of the chest is less. Pain in the abdomen, increased by pressure; right side of the thorax expanding little; no cough nor expectoration; posteriorly a slight degree of crepitating rattle can be perceived; diarrhœa. A little broth, which the patient had taken, as well as the tonic draught, were rejected by vomiting; the wine and water could alone be retained. (*Wine and water, decoction of bark.*)

31st.—The patient says he feels better; he pretends that the wine intoxicates him; the pulse continues small. Towards evening the oppression increased, the pulse became imperceptible, and the patient died during the night, having retained his faculties to the last.

*Sectio cadaveris*, 28 hours after death. The nervous centres and their membranes were healthy. The right lung, although gorged, was soft, crepitating, and torn with difficulty, especially about its middle; the upper part was sound, and nothing escaped on its being divided. The blood and tissue of the lung in other situations appeared amalgamated. The cut surface looked black, and nothing was removed from it by scraping with the scalpel. The left lung was healthy. The heart was natural; its right cavities were filled with blood from which a few bubbles of air escaped.

When the abdomen was laid open, about a pint of yellowish liquid made its escape; by pushing the bowels aside, a darker-coloured puriform fluid was observed between the stomach and liver; on the convex surface of the latter viscus there were some shreds of false membrane, loose, transparent and tearing readily. The omentum majus and outer surface of the stomach were of a red colour, owing to the accumulation of blood in the veins. Black points were scattered here and there over the small intestines. The stomach was four times as large as it is in the natural state, and appeared distended with fluid; but it was nearly empty, its walls being in many places more than an inch and a

half in thickness, and communicating to the touch the same sensation as the parietes of the abdomen when pinched between the fingers. Its mucous membrane presented six round or oval-shaped patches, black in the centre, yellow in the circumference, upon some of which the membrane could still be traced, although it was softened, and removable with the slightest touch, as if it had been in a state of putrefaction, which, however, did not appear to be the case, as no gangrenous odour was emitted. The mucous membrane was separated from the subjacent cellular membrane (which was thickened, loaded, and covered with intermingled red patches and white points), by a thick black fluid. The disorganized patches were surrounded by a yellowish areola, of varying breadth, where the mucous membrane was more consistent. Some of these were of the size of a crown piece, others considerably smaller. The mucous membrane generally tore with ease,—its natural wrinkles were effaced and it could be marked or traced upon with a very slight degree of pressure; the cellular membrane under it was thickened, and in a state at once of emphysema and œdema.

At the distance of two or three inches below the duodenum, which was healthy, there was a dusky-red spot in the small intestines, on which the mucous membrane was somewhat softened. A little lower, one of the valvulæ conniventes formed a dusky-red ridge, from the deposition within the subjacent cellular membrane of a quantity of blackish fluid which could be forced out by pressure.

On cutting through the external gangrenous tumour which had been eauterized, the cellular substance around it was found infiltrated and somewhat redder than natural. Towards the middle of the neck a quantity of blood was found effused into and between the fibres of the muscles, the cellular substance, &c., penetrating every tissue nearly to the depth of the vertebræ. The larynx was even stained. The glands of the neck were also red and enlarged, and full of dark-coloured blood. The structures on the right side of the neck as well as all the other organs of the body appeared natural.

CASE XCVII.—*Anthraxion of the eyelids. Extensive gangrene; death.*—Joséphine, a carter of mattresses, on the 12th of July, observed a small red spot, the size of a pin's head, on the outer angle of her left eye. On the 16th, this spot spread and caused some swelling of the eyelids and cheek. On the 20th, the whole of the upper and under eyelid, including the eyebrow and part of the temple, over an extent of an inch and a half in perpendicular by about the same amount in longitudinal extent, were stricken with sphacelus, and covered with a moist, brown, sanguinolent and deep slough. The outer part of the orbit was swollen and emphysematous, and the cheek, forehead, and upper part of the neck were tumid, hard, and of a violet-red colour in the vicinity of the slough. These parts were not affected as in phlegmonous erysipelas with any preternatural heat. The eyelids thick, stiff and as black as charcoal, but still moist, could not be separated from each other; so that the state of the eyeball could not be ascertained. The pulse was very small; the extremities were cold. The breathing appeared natural; the intellectual faculties were untouched. The mode in which this gangrenous affection commenced; the transformation of the spot that was first discovered into an eschar; the erysipelatous areola without morbid heat, with which it was surrounded—all these circumstances combined, led me to believe the case one of *anthraxion*, a diagnosis, the accuracy of which was subsequently confirmed by the post-mortem examination. An incision was carried along the lower eyelid in the direction of the cheek bone: it was nearly an inch deep, scarcely attended with any pain, and gave exit to a quantity of blackish blood. By separating the lips of the wound a line formed by the black and dry skin was first perceived, and under it, a dark-coloured layer, infiltrated with blood and insensible. A second transverse incision of less depth than the first, lest the eyeball should have been implicated, was made across the eyelid; and a third incision, more than half an inch deep, was carried from the alæ nasi obliquely towards the lower end of the lobe of the ear. This cut bounded the violet hue of the skin inferiorly. Along the two outer thirds of this cut the skin appeared simply red and erythematous, not sphacelated, and the adipose cellular membrane under it looked healthy. At its inner third, on the contrary, the cellular membrane presented three or four brownish spots, like ecchymoses. From the lower end of this incision a fourth was carried obliquely upwards towards the upper part of the

anti-tragus; it was about a third of an inch in depth. A certain quantity of dark-coloured blood flowed from this incision, the bleeding from which was encouraged by tepid fomentations. Dossils of lint, dipped in a strong solution of the acid nitrate of mercury, were then passed repeatedly along the surface of the different incisions. The portion of healthy skin included between the incisions was not touched with the caustic. M. Beaumetz, my dresser, sponged away the blood and sanies that flowed from the incisions; his hands remaining soiled during 55 minutes without any ill effect. Dry lint was then introduced between the lips of the wounds, and compresses impregnated with a solution of chlorate of lime applied over the sphacelated parts (*decoction of bark; sulphate of quinia 12 grains*). The patient was placed with her head well raised.

For two days this plan was pursued, and the gangrenous affection of the cheeks appeared to be arrested; but it then began to extend; gastric symptoms appeared; pneumonia made silent progress and the patient died.

*Sectio cadaveris 30 hours after death.* The interior of the cranium presented nothing remarkable. On the left side of the face the parotid gland was hard and yellowish. The portio dura of the 7th pair, at the point of its escape from this body, was unchanged; it looked slightly greenish where it passed through the gangrenous cellular membrane; by pulling this nerve gently it could be isolated from the surrounding softened structures. The veins presented no peculiar morbid appearance. The branches of the external carotid artery were unaltered. The gangrene extended below the level of the inferior incision. The skin being softened, greenish, readily separating from the subjacent tissues, and exhaling the peculiar odour characteristic of gangrene. The subcutaneous cellular substance of the eyelids and malar region was gangrenous, black, and impregnated with a greenish-coloured sanies. The masseter muscle was greenish on its outer surface; but its fibres, where they are in relation with the bone, were red and healthy. The orbicularis palpebrarum was in great part softened and gangrenous. The periosteum of the upper jaw and os frontis and parts round the orbits, was stripped off with the same ease as it is from bones that have undergone the process of maceration. The gangrene had extended to the whole of the soft parts in the same vicinity. There was, however, no trace of inflammation there,—no redness, no formation of pus. The conjunctiva was destroyed and the transparent cornea, generally opaque, was perforated with a triangular gap in its centre. The sclerotic coat and retina were healthy as were the deeper parts contained within the orbit. In the mouth an oval patch of the mucous membrane on the affected side was destroyed, and the parts with which this was in relation were green in colour. The larynx and trachea were unchanged. The lungs were gorged in some places, hepatized in others, and when cut into, the surface looked gray, purulent matter flowing from it when scraped with the scalpel. The heart and great vessels seemed healthy. The stomach presented numerous dotted red patches, an appearance which was also remarked in the small intestines and cœcum. Nothing remarkable was discovered in any other part of the body.

## VII.—PAPULÆ; PAPULAR INFLAMMATIONS. (a)

Vocab. *Papulæ.*

620. This group of cutaneous diseases is characterized by *papulæ*, that is to say, by hard and solid elevations, attended with pruritus,

(a) These are placed by Mr. Wilson, under the head of "*Depositive Inflammation of the Dermis.*" We subjoin his reasons for this arrangement.

"By the term 'depositive,' which I have selected only in the absence of a more suitable word, I mean to express that condition of the inflamed dermis in which plastic lymph is exuded by the capillary

which is always troublesome, and at times intolerable. These papulæ end by resolution and furfuraceous desquamation, and accidentally in excoriations.

621. The number of papular inflammations usually reckoned, amounts to three: lichen, strophulus, and prurigo. They might, however, with perfect propriety be reduced to two, strophulus being a mere modification of lichen peculiar to the new-born infant and suckling.

622. Papular affections may be confined to a single region of the body, upon which they occur *disseminated* or in *clusters*. The papulæ of lichen are red or inflamed; those of prurigo are nearly of the same hue as the skin in general; those of strophulus are of a vivid red, or of a dull white like the wheals of urticaria. The papulæ of lichen are scarcely so large as the head of the smallest sized pin; those of prurigo are somewhat broader; those of strophulus are very various in their dimensions. Papular inflammations have this peculiarity, that the pain they occasion is almost uniformly of the itchy kind. Lichen in its course may appear with the acute or chronic type; in prurigo the eruption is always thrown out slowly and in successive crops; strophulus presents very remarkable intermissions and exacerbations.

These three diseases may end in resolution or in desquamation; chronic lichen is frequently followed by very severe and obstinate excoriations.

623. It is only necessary to touch and to incise papulæ to be satisfied that they are solid and consistent, consequently that they are very different from vesicles and pustules, to which they bear some analogy in the particulars of size and form.

The investigation of the minute anatomical structure of these small granules is a subject of some difficulty. Their opacity and solidity, no fluid being perceptible in their interiors, even with the magnifier, are important features, besides those of a mere external nature already enumerated. But it still remains matter of uncertainty which of the elementary tissues of the skin contributes essentially to their formation. Several writers have supposed that the nervous papillæ of the skin, enlarged in their dimensions, were the parts more particularly interested; but this opinion appears by so much the less likely, as the fact is that papulæ occur but rarely on those districts of the skin which are most distinctly and abundantly supplied with papillæ, as on the palm of the hand and cushions of the fingers. Papulæ again have been supposed by Mr. Plumbe to be produced by the effusion

rete into the tissue of the dermis, so as to give rise to the production of small hard elevations of the skin, or pimples. In the preceding groups of diseases we have seen simple congestion of the papillæ of the dermis, effusion of the serous portion of the blood on the surface of the dermis, formation of pus on the surface of the dermis; but the alteration now under consideration is different from the whole of these; there is no inordinate congestion, there is no serous effusion, and no generation of pus. As far as my observation of the pathological characters of the present disease enables me to determine, there is effusion of plastic lymph into the tissue of one or more of the papillæ of the dermis, constituting a pimple of small size.

"The pathognomic symptoms accompanying pimples correspond moreover with the supposition of such a pathological structure; they are accompanied by incessant itching, a sensation which may easily be explained by reference to the moderate degree of pressure produced upon the nervous plexus of the papillæ by the effused lymph, or, probably, by the distension of the neurilemma of the nerves by the more fluid parts of the lymph, so as to affect the nutrition of the nervous substance. Pruritus is unquestionably a degree of pain, but it is one of a mild kind, and such as we see for the most part in papular eruptions of the skin, or when the dermis is returning to its natural state after inflammatory congestion of its tissue, or, again, when foreign substances, such as scabs and crusts, effused fluids, parasitic animalcules, &c., lie in contact with the skin.

"The diseases which are here characterized by the designation 'depositive inflammation of the dermis,' correspond with the order papulæ of Willan; and in this instance no difference of opinion exists among dermatologists as to the morbid affections admitted into the group."

of a very minute quantity of lymph into the dermoid tissue, with which this fluid unites when it is not re-absorbed: it is true that by pricking the larger papulæ of strophulus deeply with a needle, and squeezing them firmly between the fingers, a very minute globule of transparent serum may occasionally be expressed; but by resorting to the same procedure in cases of lichen and prurigo I have never succeeded in forcing out any thing but a drop of blood.

624. Strophulus appears particularly among new-born infants, lichen among children and adults, prurigo among children and the aged. None of these affections is contagious, but those who have been once attacked almost always experience returns of the disease under which they had laboured, at intervals more or less remote from each other, and it is observed that these relapses are particularly apt to follow atmospheric changes.

625. The papular are very distinct from the exanthematous inflammations, which present coloured blotches, not circumscribed elevations; they are not less evidently different from the bullous, vesicular and pustular forms of cutaneous affection, in which a serous or purulent fluid is effused between the external surface of the corion and the cuticle. Notwithstanding this, however, to discriminate between the papulæ of acute lichen and the minute vesicles of scabies and eczema, the eruption requires to be examined with great attention, and even to be pricked with a pin.

When the papulæ have been destroyed by scratching, or when they are replaced by furfuraceous patches or excoriations, the diagnosis is frequently so obscure, that accuracy is only at length obtained by the occurrence of fresh elevations, the formation of which being watched and discovered, that of those which may have gone before is inferred.

626. The papular inflammations are generally diseases of no great severity; though they are occasionally extremely rebellious. Various plans of treatment are practised in these cases, the activity of which ought to be in proportion to the extent and inveteracy of the eruption. Lichen *agrius* is one of the most obstinate of all the diseases of the skin.

#### LICHEN.

Vocab. *Lichen, Papulæ.*

627. Lichen is characterized by the simultaneous or successive eruption of itchy papulæ, reddish in their colour or of the natural hue of the skin, most commonly clustered together, but occasionally scattered, and occupying a particular region, or disseminated over the whole surface of the body. This affection usually ends in a furfuraceous desquamation; it terminates more rarely in superficial and very obstinate excoriations.

To make the description of the disease as complete as possible, Bateman reckoned six varieties of lichen, five of which had been determined by Willan. Some of these are marked by a particular arrangement of the papulæ, others by various modifications in the colour and in the intensity of the eruption. Lichen *simplex*, *L. pilaris*, *L. circumscriptus*, *L. agrius*, *L. lividus*, *L. urticatus*. A lichen *tropicus* has also been since admitted, a title under which the whole of the lichens developed within the tropics, and exasperated by the effects of excessive temperature have been included. These, however, do not actually constitute diseases different from one or other of the varieties already recognized.

The different forms of lichen occasionally occur with the acute type; but they are much more frequently chronic in their progress.

628. *Symptoms.*—1st. Lichen *simplex* may appear confined to a single region of the body,—to the face, neck, arm; or it first attacks one or other of these, the face and arm for instance, and spreads within the course of three or four days to the trunk and lower extremities, attacking particularly the external and posterior aspects of the limbs.

Lichen *simplex acutus* is characterized by small solid elevations of a red colour, not transparent, frequently acuminated, containing neither pus nor serum, and seldom exceeding a millet seed in size. This eruption is attended with a disagreeable sensation of tingling, espe-

cially during the night. The eruption, irregularly scattered over the skin, continues unchanged for seven or eight days, after which its red colour changes, and it ends in furfureous desquamation.

Lichen is seldom ushered in by constitutional symptoms,—fever, general uneasiness, &c., except in those cases in which the eruption is very abundant.

Although each individual papula does not continue longer than a week, lichen *simplex* may remain as a disease during many months, and even during several years. It then consists of a succession of eruptions,—Lichen *simplex chronicus*. Whilst one is disappearing another is evolved, and the disease in this way invades many different regions of the body, one after the other. Frequently when the cure seems accomplished, a fresh crop of papulæ breaks forth, in one case apparently from some change in the weather, in another from some moral cause, or some error in diet. In the majority of instances the fresh eruption is not heralded any more than the first attack by a febrile paroxysm; this phenomenon in fact is only observed during the course of the disease when the eruption is extremely abundant, or is complicated with some other inflammatory affection. Willan was mistaken when he imagined that lichen *simplex* was always preceded by febrile symptoms, and gave this circumstance a place in his general definition of the disease.

Lichen *simplex* may pass into the state of lichen *agrius*; the papulæ are then surrounded with a slight reddish areola, and appear to become confluent; the whole of the eruption does not always share in this exacerbation, which is occasionally observed to give a favourable turn to an eruption of long standing.

2d. Lichen *pilaris*. This variety does not differ from the preceding save in this: that the papulæ are evolved on points of the skin which are traversed by hairs. The bulbs of these seem occasionally to participate in the inflammation, which is always deeper than in lichen *simplex*. Lichen *pilaris* is almost always chronic in its nature; it is not uncommon to see it continue for several years.

3d. Lichen *circumscriptus*. This variety is characterized by one or several clusters of papulæ, pretty regularly circular in their shapes, and bounded by a well-defined edge. It occurs with particular frequency on the back of the hand, on the forearm, ham of the leg, and region of the sternum. The course of this variety is nearly the same as that of lichen *simplex*; it is, however, somewhat less obstinate. Some of the patches remain stationary for a certain time, and then get well spontaneously from the centre towards the circumference of the groups. Others of the patches, again, extend gradually, by means of fresh circles of papulæ, which, thrown out around the first formed, increase in size, and finish by becoming blended with them. Eruptions of papulæ clustered together in this way are in general less inflamed than the scattered granules of lichen *simplex*; I have frequently remarked them nearly of the same colour as the skin. At the same time that the edges of the groups extend, their centres become level or smooth, acquiring a pale rosy colour, with a slight tinge of yellow intermixed, and a furfureous aspect. Whilst the first formed clusters are undergoing the process of desquamation, new patches are developed, which terminate in the same manner as those that have gone before them. The disease is in this way prolonged indefinitely. In some cases the papulæ are arranged in small stripes, so as to simulate a rough line, which I have seen forming a kind of collar in front of the neck, extending from one ear to the other,—lichen *gyratus*.

4th. Lichen *agrius* is distinguished by its prominent and acuminated papulæ, of a vivid red colour, and running one into another over an erythematous surface, itself surrounded by a very marked red blush. The eruption of the papulæ in this variety is frequently accompanied with a febrile state, which commonly yields when this is accomplished. These papulæ cause a burning and intolerable sense of itchiness, especially during the night, and which is exasperated by irritation of every kind. The pruritus occasionally amounts to a kind of torture; patients not content with scratching themselves with their nails, which they do incessantly, seem to feel peculiar pleasure in tearing their skin with the roughest brushes they can lay their hands on. By these measures, as may be imagined, the points of the greater number of the papulæ are torn off; the skin becomes red and bleeding; a serous fluid exudes from the torn apices of the

papulæ, and concretes in the shape of yellowish crusts, somewhat rugous to the eye, but soft and very slightly adherent in fact. This advanced and very severe form of lichen *agrius* has been assimilated by Alibert with the excoriations of eczema, and included by him in his description of the *dartre squameuse humide*.

In the severe lichen *agrius* of old standing, the skin is dry, rugous, hard, and cleft with deep furrows, especially about the bends of the arms and hams, when these parts have been the seat of the eruption. These altered surfaces long remain dry and unyielding even under the influence of the vapour bath.

Lichen *agrius* is a form of disease that is pretty frequently encountered. It has no more certain term of continuance than the varieties that have already been enumerated. It may come to an end in the course of eight or ten weeks, or continue for months and even for years, the eruption never presenting more than simple remissions more or less remarkable. The disease is very apt to recur on changes in the state of the weather, when it has existed long on any one place, or when it has already attacked the same district of the skin oftener than once.

During the continuance of lichen *agrius* pain in the epigastrium, nausea, vomiting, diarrhœa, and several other functional disturbances of the digestive organs are occasionally complained of.

5th. Lichen *urticatus* is a variety which was first described by Bateman, and by him added to those already admitted by Willan, being designated on account of the analogy which it bears in several particulars to urticaria. Lichen *urticatus* is observed occurring more especially on the neck and lateral parts of the face; it is frequently attended with febrile symptoms, and appears and disappears within a short space of time. The papulæ which characterize it are of an irregular shape; they very much resemble the swellings produced by the bites of bugs or gad-flies, and are mixed with small inflamed and itchy papulæ. Whilst these first-formed papulæ are ending in resolution, or desquamation, others are appearing successively on the trunk and extremities, where they become confluent, and form small patches. Lichen *urticatus* is a rare disease; I have never met with it except during the heats of spring and summer. In young children the strophulus *candidus* appears to correspond with this variety of lichen in adults.

6th. Lichen *lividus*. Under this title Willan has described a papular eruption of a dusky or livid colour, occurring principally on the extremities, and being unattended with febrile symptoms. It is apt to return after having disappeared, and may thus continue during an interval of several weeks. This variety of lichen is very uncommon. I have myself only seen two cases of it, both of which occurred in individuals whose constitutions had suffered from moral causes, as well as physical privations of every description.

7th. Under the head of Lichen *tropicus* have been included the whole of the varieties already enumerated, but developed under the influence of a tropical temperature. The papular disease engendered under tropical latitudes has been successively studied by Bontius, Cleghorn, Johnson, &c., whose several descriptions of the malady differ in no essential circumstance. In these countries, says Bontius, when the body has been covered with perspiration, an eruption of red and rough papulæ is apt to take place over the whole surface from the head to the feet, attended with a very troublesome pruritus. This disease attacks those persons more particularly who have recently arrived from colder climates; but no one is at all times exempt from liability to its invasion. When the skin is torn by the nails, excoriations frequently follow, which prove very rebellious to every form of treatment. The pruritus, according to the same author, is best alleviated by keeping the parts attacked covered with folds of linen dipped in water, mixed with vinegar or orange juice. This application at first causes acute pain, but this soon passes off, and the pruritus then becomes more endurable.

Cleghorn expresses himself nearly in similar terms: the cutaneous eruption entitled *prickly-heat* is so common in warm countries, that almost all suffer in a greater or less degree from it during the hotter seasons of the year. Children, however, seem more subject to it than the grown up and the aged. The eruption consists in an immense number of small round and red elevations which appear on different parts of the body, particularly after active exercise. Whilst

the eruption continues, the only inconvenience suffered arises from the pruritus attending it; but if it happens to be driven in by exposure to cold, by using the cold bath, or committing any imprudence in regard to diet, very serious symptoms may ensue. The moment that feelings of general uneasiness, pain in the head, excessive heat of the surface, &c., proclaim the recession of the lichen, blood-letting, and aperient and cooling acidulated diluents are to be had recourse to.

Dr. James Johnson was himself attacked with lichen tropicus. "The sensations," says he, "arising from prickly-heat are perfectly indescribable, being compounded of pricking, itching, tingling, and many other feelings, for which I have no appropriate appellation. It is usually but not invariably accompanied by an eruption of vivid red pimples, not larger in general than a pin's head. This eruption often disappears in a great measure when we are sitting quiet and the skin is cool; but no sooner do we use any exercise that brings out a perspiration, or swallow any warm stimulating fluid, such as tea, soup, or wine, than the pimples become elevated so as to be distinctly seen, and but too sensibly felt. Many a time I have been forced to spring from the table and abandon the repast I had scarcely touched, to writhe about in the open air; and often have I returned to the charge with no better success. The night affords no asylum. For some weeks after arriving in India I seldom could obtain more than an hour's sleep at one time, before I was compelled to quit my couch, and if there were any water at hand, to sluice it over me, for the purpose of allaying the inexpressible irritation."<sup>1</sup>

Hillary recommended that the evolution of the eruption should be favoured by the use of warm diluents, tea, coffee, &c. Dr. Johnson with greater reason sees no advantage in suffering from such a disease; and to prevent it entirely he advises Europeans arriving in India and warm climates to clothe themselves lightly, to avoid all exertion during the heat of the day, to live temperately, &c. In every instance in which this excellent author observed the recession of the lichen tropicus he could trace it to the occurrence of some other disease of greater or less importance.

629. The essential and distinguishing features of lichen are its red and inflamed papulæ; when other alterations are observed occurring at the same time as these papulæ, they constitute true complications. Thus, amidst the papulæ of the various species of lichen, and especially of lichen agrius, a number of small adventitious vesicles, are occasionally perceived, similar to those of scabies or eczema. The presence of these vesicles might even mislead in the establishment of a diagnosis, without attention to the circumstance of their appearance anteriorly to the evolution of the papulæ, and to their numerical amount, which is much inferior to that of the papulæ. Such vesicles must be regarded as a temporary complication, produced by the intensity of the papular inflammation of the skin. Lichen is occasionally observed to complicate scabies, when this disease attacks a young, plethoric, and robust individual. It happens more rarely that psoriasis appear and blend with the papulæ of lichen, in which case the diagnosis is attended with great difficulty. Incrustations of various thickness and extent speedily cover a part of the diseased surface, and may cause a truly lichenous eruption to be mistaken for an eczema impetiginodes; it frequently happens, indeed, that it is only after the disappearance of these adventitious inflammatory affections that the really papular character of the principal eruption can be clearly ascertained. I have also met with lichen complicated with ecthyma and furuncle.

Lichen is very rarely observed to be replaced by any other form of eruption.

After several relapses, or when lichen has continued long on any region, the skin always wears a dirty or grayish-yellow aspect, and becomes to a remarkable degree thickened and rough, so as to appear even scabrous.

630. Independently of the varieties which lichen presents, according as the papulæ which characterize it are scattered or arranged in clusters, are slightly or very much inflamed, are thinly sown or so thick as to be confluent, it presents several peculiarities according to the region of the body upon which it is evolved.

1st. Lichen of the face is common during summer among individuals whose features are habitually exposed to the burning rays of the sun.

The furfuraceous desquamation with which it terminates has been described by several French pathologists under the title of *dartre farineuse*. When lichen of the face becomes chronic, the skin of the nose, malar regions and chin, which is the usual seat of this eruption, becomes yellowish, dry, and furfuraceous. It is readily flushed by the influence of external warmth, spirituous liquors, the approach of the menstrual period in females, &c., and then assumes a coppery-red colour. This variety of the disease is extremely intractable, especially in women arrived at the critical age.

2d. Lichen of the extremities occurs particularly on their posterior and outer aspects, and in the bends of the arms and popliteal regions; the inner aspects of the legs and arms are often observed totally unaffected when the surfaces directly opposed to these are covered with papulæ. The arms and forearms of cooks, founders, smiths, &c., habitually exposed to high temperatures, are frequently attacked with lichen simplex, or an artificial papular eruption having the same characters.

3d. Lichen of the genital organs and margin of the anus is the most rebellious and insupportable of all the varieties of this eruption. It is frequently difficult to distinguish this eruption from eczema of the same parts when it has advanced into the furfuraceous state, or is attended with a sero-sanguinolent discharge as it frequently is § 353. Still a few papulæ may almost always be detected in the neighbourhood of the furfuraceous, red or excoriated surfaces when the case is one of lichen.

4th. Lichen very seldom attacks the hairy scalp primarily; but when the disease is evolved on the nucha, forehead or temples, it may spread to the neighbouring regions covered with hair. A violent pruritus and furfuraceous desquamation are then the principal characters of the disease.

631. Causes.—Lichen attacks individuals at every period of life. Children of a bilious habit, adults and individuals of a nervous and irritable temperament are particularly predisposed to it. Infants at the breast are often attacked during dentition with eruptions having the characters of lichen. The temperature of the atmosphere during spring and summer, has a very marked influence on the appearance of this eruption, which is observed to recur in some individuals regularly for several years during the hottest season. Lichen agrius most usually appears among individuals addicted to the use of spirituous liquors. Gastro-intestinal inflammations and the causes which produce them are occasionally observed to precede the appearance of the eruption.

632. Diagnosis.—It seems impossible to mistake even the most copious eruption of lichen simplex for the efflorescence of measles, scarlet fever and the other exanthemata. There is too marked a difference between the blotches or stains of these diseases and the elevated papulæ of lichen. Scabies and prurigo are the affections with which lichen simplex is most apt to be confounded. In prurigo, which like lichen is a papular disease, the papulæ are larger, flatter and nearer the natural colour of the skin—they are not red and flushed like the eruption of acute lichen; prurigo is attended with a burning pruritus, whilst the morbid sensations attending lichen are usually of a tingling and tickling description; in lichen, indeed, it is common enough for patients to make no complaint of pruritus except when the body has been exposed to heat, or the system has been stimulated by some imprudence in diet, particularly by the ingestion of some spirituous or fermented liquor. The distinguishing character of scabies is the vesicular form of its eruption; lichen, on the other hand, is papular in its origin and progress. The vesicles of scabies are almost always distinct, scattered over the inner aspects of the arms, forearms and wrists, between the fingers, and upon the front of the abdomen. The papulæ of lichen are generally agglomerated, and appear in preference on the outer and posterior aspects of the extremities. In some rare cases, the hands are the seat of lichen simplex; but these papulæ are then commonly clustered on their dorsal aspects, whilst the vesicles of scabies are principally observed between the fingers. The papulæ of lichen, especially when they are confluent, are surrounded by minute, thin and flimsy squamæ; the vesicles of scabies are never covered except by small scabs. Lorry, whilst speaking of lichen, under the title of papulæ, gave long ago the principal characters which distinguish it from scabies. He says: "The eruption of papular syphilis (lichen syphiliticus) resembles that of lichen urticatus in

<sup>1</sup> Influence of Tropical Climates, 3d edit., p. 17, 8vo. Lond., 1821.

point of size; but it is coppery in colour, is not the seat of incessant pruritus, and is accompanied with other symptoms of lues."

When patients labouring under lichen *agrius* tear the summits of the papulæ, there exudes a sero-sanguinolent fluid which dries up into small thin and adhering scabs; no true incrustation, however, is ever formed in lichen such as is observed covering the pustules of impetigo.

The characters of lichen *circumscriptus* are generally so well defined that it is next to impossible to confound this with any other papular or squamous eruption. And yet when the patches of lepra are coming to a close, when the skin has regained its natural condition in their centres, and their edges are divided into a multitude of minute red points, raised above the level of the integuments, they might be mistaken for the remains of lichen *circumscriptus*. But by carefully examining these points, whose shape is irregular, they will soon be seen to want the characters of papulæ.

The diagnosis of lichen *agrius* presents some difficulty when the eruption is so crowded that the individual papulæ cannot be perceived. On the margins of the patches, however, a certain number of papulæ may always be detected, which then proclaim the actual nature of the disease. The confluent and lacerated papulæ of lichen *agrius* might very readily be mistaken for the superficial excoriations consequent on an eczema, did not the few papulæ or vesicles that almost uniformly escape uninjured in the circumference of these excoriations reveal the kind of malady with which we have to do. The thickening of the skin that takes place in lichen *agrius* is another feature which by itself very commonly serves to distinguish this disease from any other with which it is at all likely to be confounded.

The small pustules of impetigo are occasionally clustered like the papulæ of lichen *agrius*; but in the lichen the scabs that occur are very thin and adherent, whilst in the impetigo they are thick and easily detached. Psoriasis has well-marked characters that distinguish it from lichen *agrius*. The successive desquamation that so particularly characterize psoriasis, happen along with a thickening of the corion, and especially of the cuticle, which is never observed to the same amount in lichen. Further, a number of papulæ are almost invariably found on the margins of lichenous patches even when the disease is of the most violent description, and has been most severely irritated.

The pustules of rosacea are inflamed at their base like the papulæ of lichen *agrius*, but they do not ulcerate; each of them contains a minute globule of pus, whilst the papulæ of lichen are solid, and discharge from their excoriated points a sero-purulent fluid which moistens their surface. The papulæ congregated on any region, whatever its extent, advance simultaneously, become confluent, and are attended with an irritation which extends to the corion, but rarely to the subcutaneous cellular membrane; in rosacea of any severity the irritation always extends to the cellular tissue, and there leaves enduring traces of its presence. Lichen *agrius* of the face frequently attacks the forehead, face, and lips; rosacea has its principal seat on the nose and cheeks. Rosacea is attended with a kind of tingling which becomes more marked and more troublesome after meals, on approaching a fire, and in warm places. The pruritus of lichen *agrius* of the face is more violent and seems more deeply seated; it occasionally becomes intolerable during the night and after the ingestion of any stimulating fluid. The discharge from the small acuminate pustules of rosacea often changes into thin scabs which are speedily detached; the excoriated papulæ of lichen *agrius* of the face also become covered with minute scabs, but they are thinner, broader and blend more generally with the furfuræ of the epidermis than those of rosacea.

653. *Prognosis*.—The continuance of simple lichens occasioned by the heats of summer varies from one to two or three weeks.

When lichen is the effect of causes unknown, or which have not acted directly upon the skin, it is generally difficult to speak with any degree of certainty with regard to the period of its probable termination. It is occasionally very obstinate, and may continue, whatever the disposition of the papulæ, for several months and even during several years. Lichen is in general the more troublesome and the less under the influence of remedial means, as it is of older date and has been characterized by successive eruptions occurring in individuals further advanced in years, and with more seriously shattered

constitutions. Lichen *agrius* of the face is commonly very rebellious and particularly apt to recur. I have scarcely seen more than two or three cases in which this papular inflammation appeared to be critical and salutary; to individuals otherwise in good health it is an insupportable affliction, rendering their lives truly miserable.

634. *Treatment*.—I could easily quote many cases of lichen *simplex*, and of lichen *circumscriptus* and lichen *urticatus* in which cures were accomplished by the sole effects of regimen,—by a regular and unexciting plan of life.

Whatever the form of lichen, whether the papulæ are widely scattered, or collected in clusters, if the disease be of recent date, acute in its character and of no great extent, a cooling regimen, slightly acidulated diluents and the use of the temperate bath, or of the cold river bath during summer, generally prove sufficient to make it disappear, and this without risk of ulterior ill effects. The tepid and hot bath frequently aggravate the symptoms of the eruption, particularly of the variety entitled *urticatus*.

When the disease has withstood this plan of treatment, recourse must next be had to the internal administration of the nitric, muriatic and especially of the sulphuric acid in large doses. These mineral acids, when they seem to engender any considerable degree of irritability of the digestive organs, must, however, be replaced by some of the less active vegetable acids such as the citric and acetic. As a final measure and when the papulæ are extremely numerous, agglomerated and confluent in various places, as they are in the lichen *agrius*, if the patient be young and of good constitution it may be necessary to detract blood once or oftener. General blood-letting is indeed an indispensable measure when the eruption is not confined to any determinate region of the body, such as the hand, face, &c. When blood is abstracted locally, the leeches employed must always be attached beyond the circle of the eruption; as without this precaution the irritation of their bites is apt to aggravate instead of relieving the local inflammation. All topical applications should be of the mildest description, and used cool or cold to the affected parts. Soothing washes, and gelatinous or mucilaginous baths, are generally useful when applied at low temperatures. Patients should, at the same time, be put upon the use of one of the acids which have been mentioned, combined as a sherbet, and should be advised to dress themselves with soft under garments and such clothing as will not tend to excite or increase the heat of the body.

The effects of these various means ought to be seconded by a regimen of greater or less severity according to the state of the constitution. Patients must at all events abstain from spiced food of every kind, spirituous liquors, in a word, from all that could possibly tend, by its stimulating qualities upon the stomach, to produce at a later period any thing like a determination to the skin.

635. When lichen consists of several successive eruptions, and has assumed the chronic character, if the constitution of patients appears to have suffered from age or any other cause, the practitioner should be careful to strengthen it as much as possible by the exhibition of tonics, and the recommendation of a suitable regimen, even before he thinks of attempting to treat the eruption.

When the disease is of very long standing, and affects the integuments deeply, the affected parts are often slightly anointed with the following ointment with the greatest advantage: R. Adipis suil. ʒi; Sulphur. sublim. ʒi; Potassæ subcarb. ʒss. Emollient temperate baths are to be used at the same time, and after some little interval has elapsed they may even be taken slightly alkaline. Under similar circumstances I have frequently prescribed either of the following unguents with excellent effects: R. Adipis suil. ʒi; Colomelan. ʒi; Camphoræ gr. xviii; R. Adipis suil. ʒi; Hydrarg. deuto-ioduret gr. x. M. I have also occasionally succeeded in giving relief from the pruritus by cauterizing the affected parts of the skin very slightly with nitrate of silver, or by the use of vinegar and water as a lotion.

The vapour bath, very detrimental in acute lichen, becomes extremely beneficial in the chronic state of the disease, especially when the surface of the skin feels very dry. I have treated a great many cases of these eruptions by the combined use of the vapour bath, and the internal exhibition of the muriatic acid sherbet.

Sulphureous baths, so generally and indiscriminately recommended in the treatment of cutaneous affections, are constantly hurtful in acute

lichen, and very seldom serviceable in the chronic form of the disease. These baths may even cause a lichenous eruption; it is by no means an unfrequent circumstance to see lichen *agrius* appearing among individuals under treatment for scabies by means of sulphureous water bathing. Nevertheless, I have obtained the cure of several cases of obstinate *hereditary* lichen, apt to return at frequent intervals, by effecting a material modification of the constitution by the use of artificial sulphureous water baths prolonged during several hours every day. Results of a similar description have been observed from the natural baths of Louesche and Schinznach.

In lichen *agrius* advanced to the state of excoriation, the *mineral acids* ought constantly to be prescribed, unless, indeed, the irritable state of the digestive organs seems to contra-indicate their use. They should be taken in doses of from half a drachm to two scruples a day, in a pint of water sweetened to the taste. They cause a diminution in the watery secretion poured out by the torn papulæ, and appease the pruritus.

A certain number of cures have also been obtained by the exhibition of *saline purgatives* frequently repeated, or of four or five grains of calomel combined with eight or ten of rhubarb, or the same quantity of jalap; to me, however, the mineral acids have generally appeared more efficient as therapeutic agents in this class of complaints.

When *chronic* lichen has withstood these various plans of treatment in an individual otherwise in good health, exempt from visceral affections, &c., when the disease is hereditary, is dispersed over a large surface of the body, and occasions distressing insomnia, we must then have recourse to some of the preparations of *arsenic*, and continue this class of medicines for a long time in graduated doses, it being always understood that they shall produce no manifestly injurious effects on the constitution. I have succeeded in removing several *circumscribed lichens* of old standing by the internal use of the solution of the arseniate of soda, and of sulphurated alkaline inunctions. These remedies, however, it must be presumed, are only to be employed in the small number of cases in which all other means have been fruitlessly enforced, and the disease has attained such severity that patients, worn out and reduced to despair, insist on getting rid of their infirmity at all hazards. It is further necessary, before prescribing these active medicines, to inquire particularly into the state of the digestive organs, only to increase the doses very gradually, and above all not to exceed from fifteen to twenty drops daily of Fowler's, or a drachm of Pearson's arsenical solution for an adult, in some mucilaginous fluid. Should such old and obstinate eruptions decline at all in severity and become endurable, it is often prudent not to expose patients to the evils that may result from the use of arsenical preparations. It is very necessary to be on our guard against any determination, speedily and at all risks to subdue these inveterate affections of the skin. When they have appeared before the age of puberty, they may get well of themselves a few months or a few years later, or at all events with the assistance of medicines less dangerous in their action. In adults, too, and individuals of riper years, an appropriate regimen pursued during several months frequently renders a cure easy which had formerly appeared impossible even under the influence of the most active medicinal means.

#### History and particular Cases.

636. Hippocrates classes the lichens with prurigo, psoriasis, and lepra, without specifying the particular characters of each.<sup>1</sup> According to De Gorter<sup>2</sup>—"In hoc loco Hippocrates per *lichenas* intelligit talem cutis fœdationem, in quâ summa cutis *pustulis siccis* prurientibus exasperatur." By *dry pustules* De Gorter himself evidently understands *papulæ*. Celsus appears to have referred to lichen in his description of *papulæ*,<sup>3</sup> and Lorry in very recent times has treated of this disease under the same title. The Latin translators of the Greek writers have erroneously rendered the word *lichen* by *impetigo*, Celsus having already used the Latin term in another acceptation, which is adopted at the present day to signify a pustular inflammation. It is not unimportant to observe in this place that F. Platerus has

spoken of lichen under the name of *scabies sicca*. "Scabies sicca seu scabrities, quæ pustulis siccis e quibus nec sanies nec pus emanat, se prodit cutemque asperam reddit et crosam cum pruritu plus minusve molesto."<sup>4</sup> Others have mentioned the disease under the title of *scabies agria*. Willan and Bateman were the first who gave an excellent description of lichen. Several of Alibert's observations relative to his *dartre furfuracée volante* appear to assimilate themselves to the lichen; he has, however, recently described the disease under the name of *prurigo lichenoides ou furfurant*. Bertrand Lagresie has detailed a case of it under the very objectionable title of *dartre miliaire*.

Bontius,<sup>5</sup> Cleghorn,<sup>6</sup> and Dr. James Johnson<sup>7</sup> have severally studied the disease as it occurs within the tropics.

I shall now give a few cases of the principal varieties of lichen; others may be found by referring to the Journal Hebdomadaire, t. vii. pp. 436, 459, the Revue Médicale, Juin 1830, p. 541, and the Lancette Française, 1831, t. v. p. 581, &c.

CASE XCVII.—*Lichen simplex of the face*. Max. Degr., mason, seventeen years of age, came into the Hôpital Beaujon, on the 11th of September, on account of a coryza, a slight bronchial affection, and a lichenous eruption of the face. For four or five days the patient had complained of intense pruritus of the face, the skin of which had in several places become rough and uneven, and it was easy to perceive that the lower part of the countenance was beset with numbers of small red and *solid* elevations. The greater number of these were acuminated, others were semi-globular. The recent papulæ were principally situated on the chin. In one place they were disseminated, in another collected into clusters; many were visible which the patient had deprived of their heads with his nails. The great majority presented a small brown scab which might have been covered with the head of a pin; several were already free from this incrustation, which was succeeded by a small red point. The parts of the integument upon which these alterations appeared were covered with furfuræ, and beset with small untouched papulæ. This mixture of papulæ intact, and of papulæ lacerated, or in a state of desquamation, was particularly remarkable upon the cheek and about the commissures of the lips; on the upper lip the papulæ were shrunk and replaced by a furfuraceous desquamation. Neither with the naked eye nor with the assistance of a magnifier could either pus or serum be detected in any of the entire papulæ.

No other region of the body presented any trace of a similar eruption. Under the sole influence of the antiphlogistic regimen, the use of the cool bath and of diluents, the papular inflammation of the face, coryza and slight bronchitis with which it was complicated, had completely disappeared by the 22d of September, 1826.

CASE XCIX.—*Lichen of the trunk and extremities*. M. Rousset was admitted a patient at the fourth dispensary on the 19th of August, 1822. The papular inflammation under which the patient laboured had appeared towards the end of June of the same year, by a number of small pruriginous elevations upon the right thigh. The eruption spread on the following days to the opposite side of the loins and thorax. For some time Rousset gave little heed to this affection, but it at length became so troublesome, and was attended with such violent pruritus, that in his own words, "he would gladly have stripped off his skin to be rid of it." This state was unaccompanied with fever, or any derangement of the principal organs.

A very great number of minute red, acuminated, solid elevations containing no fluid, were conspicuous on both the upper and lower extremities, and scattered over the trunk. The fingers passed over the surfaces of the skin that were thus affected, distinguished inequalities similar to those of shagreen. The papulæ, crowded together and disposed in irregular clusters on the forearms, were disseminated over the arms; on the anterior part of the chest, the eruption, confluent in some places, formed in others broad red papular patches, separated from each other by intervals of healthy skin. These clustered patches, where the papulæ were confluent, were the

points in which the patient complained of the pruritus as most intolerable. Here and there, between the inflamed papulæ, small surfaces were remarked upon which a furfuraceous desquamation was going on; traces of scratches and a number of small black scabs that might have been covered with the head of a pin, and corresponded to the heads of papulæ the apices of which had been removed with the nails, were also observed in different situations. (*Barley water with honey; V. S. B. ad 3xii; vegetable diet.*) The effects of this treatment were very remarkable. On the 22d of August, however, there still remained a great number of papulæ upon the skin, but the pruritus was very supportable—(*same drink and diet; warm bath.*) The warm bath was taken twice, and followed each time with a fresh eruption of papulæ. The pruritus was increased during the day by exposure to heat and exercise. On the 24th of August he was again bled from the arm to the same extent as before: next day the papulæ most recently evolved were shrunk; in other places the affected skin was covered with a furfuraceous desquamation, and the freshest papulæ within a short time became affected with the exfoliation. On the 10th of September the patient had recovered completely.

CASE C.—*Lichen; blood-letting and diluents; cure.* Regnault, a dyer, 25 years of age, in the habitual enjoyment of good health, consulted me on the 26th of August, 1822, on account of an eruption which had made its appearance, under the form of numerous small red and solid elevations, on the forehead, arms, and breast, between the 12th and 14th of the month. The parts affected were extremely itchy, and the sensation was much exasperated by exposure to the heat of a fire. Where the eruption was very close, as upon the forehead, the skin had a punctuated appearance, and the finger passed over it, detected numerous irregularities occasioned by the prominence of the individual papulæ. On the forearms and wrists the eruption occurred in irregular clusters of various sizes, which felt like pieces of fish-skin. A certain number of the papulæ composing the whole of these groups were shriveled and succeeded by a furfuraceous desquamation; these patches, indeed, formed true papular rings, in the centre of which the skin looked mealy and somewhat yellowish in colour. The papulæ in the neighbourhood, and those generally that were most remote from the centre, were of a vivid red. The heat of the skin was not essentially increased, and the functions of the whole of the principal organs were performed with perfect regularity. The patient was put upon a course of diluents, and was bled twice. Within a fortnight he had recovered completely.

CASE CI.—*Lichen circumscriptus. Gelatinous baths and purgatives.* Madeleine J. D. Fleury, 18 years of age, of a nervous temperament, was presented to me on the 5th of March, 1826, for my advice on account of lichen circumscriptus. The disease had commenced in February, 1825, by a cluster of elevations on the left leg, and since this epoch others had appeared on almost the whole surface of the body. Various remedies had been fruitlessly tried for this eruption. The application of an ointment of red-precipitate had increased it greatly. A blister had been applied to the arm and kept open for five months. On the 15th of March, 1826, the following appearances were distinguished:—

1st. Over the face, and especially the forehead, cheeks and ears, broad mealy-looking spots or patches, on the surface of which several papulæ were apparent. No affection could be discovered of any part of the hairy scalp.

2d. On the body, and particularly on the nipples, several clusters of papulæ of an oval or irregular shape, the centres of which were in a state of desquamation. On the back several other clusters of various sizes, composed of papulæ, some of which were red and inflamed, and others, probably of old standing, presented a slight yellow tinge.

3d. On the upper extremities, and particularly on the outer and posterior parts of the forearms, several papular clusters an inch and a half in diameter were distinguished, whose centres were desquamating. The papulæ nearest the centre were yellowish, those more remote were red and inflamed. On the print of a blister, several very distinct papular elevations were very conspicuous.

4th. On the lower limbs traces of a similar papular eruption were not less apparent. Some of the groups were here fading, of a yellowish or brownish hue, and covered with furfuræ; others were fiery, their primary form being still very distinct.

Although the papulæ in general did not appear very violently inflamed, the eruption was attended with very troublesome pruritus, particularly when the heat of the surface was increased by exercise or the warmth of a bed. The skin was rough and dry on the parts affected. Twenty-five gelatinous baths, and a purge administered every fifth day, had a singular influence in diminishing the eruption. Several fresh clusters of papulæ, nevertheless, made their appearance on the trunk and extremities; but twenty more of the gelatinous baths being taken, the skin presented no further trace of eruption.

CASE CII.—*Lichen of the bends of the arms and hams. Inunction of an alkaline sulphur ointment.* N \* \* \*, six years of age, had laboured from her birth, under a lichen agrius. In other respects the child was in apparent good health. On the 14th of June, 1814, this patient presented the following morbid appearances:—the skin of the face, except that of the chin and lips, was healthy. The latter parts were not swollen, but their integument was dry, rough and mealy, and here and there presented slight superficial chaps, a few papulæ, scarcely inflamed, and some, the summits of which had been torn off, and were now covered with small dark-coloured incrustations. On the upper extremities the papulæ were confluent and clustered; at the bends of the arms the skin was red and inflamed, and surmounted by a number of papulæ in different states, entire, or torn on the tops. Several small chaps and scratches were also visible, and different points were affected with furfuraceous desquamation. On the legs an eruption of papulæ, altogether analogous, was evident, scattered over the outer and back parts of the thighs, agglomerated in the hams, where the skin was red and dry, and chapped and torn with the nails in different places. The child complained of violent pruritus, and during the night tore herself with her nails. I prescribed the gelatinous bath and citric acid sherbet, which were continued for a month, without any other effect than some diminution of the itching and of the redness of the skin in the folds of the arms and popliteal regions; for as one crop of papulæ terminated in a furfuraceous desquamation, others were evolved. I now determined to try stimulus of another kind to the skin than that to which it had been so long accustomed. The affected parts were rubbed daily with an alkaline sulphur ointment. These frictions which were continued for about ten minutes, were not attended at the time with any unpleasant sensation; but in about a quarter of an hour afterwards, the little patient complained of rather a violent sense of scalding in the parts to which the ointment had been applied. This ointment had not been used above eight or ten times before a general redness of the skin replaced the papular clusters. This excitement disappeared in the course of twenty-five days, and the skin of the bends of the arms resumed its natural appearance. The eruption proved more obstinate in the hams; but it yielded there eventually, and by the 15th of Sept., 1824, the patient was quite well.

CASE CIII.—*Lichen of the genital organs, &c. Blood-letting, whey, and vinegar washes.*—N. Martin, an omnibus driver, aged forty-eight, drinking wine and spirits freely, but not to the extent of intoxication. Within ten years he had contracted the itch thrice.

On his admission into the Hôpital de la Charité, on the 23d of November, 1833, he had already laboured, for a fortnight, under a lichenous eruption which spread over the genital organs, and upper and inner parts of the thighs, extending back all the way along the cleft that separates them. Over-indulgence in spirituous liquors had some time previously produced congestion towards the head, for which the patient had been let blood three different times, at short intervals. A more sober life had recently prevented the recurrence of this symptom, when a sensation of heat and itchiness began to be felt around the anus; it was of no intensity at first, but increased so much within a few days that the patient felt compelled to endeavour to relieve himself by frequent scratching. The eruption soon spread to the penis and scrotum, and the pruritus was now so violent that the patient was glad by tearing himself with his nails to replace this sensation by a more endurable one of painful smarting. Lotions with a solution of the super-acetate of lead did no good. The slightest freedom in regimen rendered the pruritus insupportable. The patient at length was entirely deprived of sleep; the heat of the bed increased his misery to such a degree that he lay without covering of any description. The surface of the diseased skin has always been dry, of an intense red colour, furrowed by traces of the nails, hotter than

the neighbouring parts, and shining in the centre of the clusters. The extent of the disease is indicated by a kind of raised edge, rough to the touch, and composed of coherent and not very distinct papulæ. The penis and scrotum are uniformly red. No traces of any functional disturbance could be detected. (*V. S. B. ad 3xii; two measures of nitric acid sherbet; fomentations with cool decoction of althea; temperate bath; milk and vegetables for diet.*)

Nov. 24th.—The patient was sensibly better, the pruritus less urgent; but he had slept very little. The blood abstracted presented a thin buffy coat; the coagulum, however, was very much contracted. The treatment indicated was continued till the 28th, and the affected parts were twice anointed with lard. The patient feeling himself worse was bled again on the 29th. This measure gave relief, but only for a few hours; this time the blood was not buffed. On the 30th, vinegar washes were resorted to with a view to allay the itching. The application of compresses dipped in this wash was found immediately to moderate the pruritus; it was necessary, however, to renew them frequently, and the colder they were the patient felt the greater relief. Dec. 6th.—The redness of the skin was greater, and a kind of smarting sensation had succeeded to the violent pruritus. The lotions were now discontinued. Dec. 7th.—The temperate water-baths were replaced by those of watery vapour, and these were repeated constantly till the 11th, when, as they seemed to excite the patient too much, the skin acquiring a purple red colour, they were discontinued, and the simple water-bath recommenced; the nitric acid drink was carried the length of three pints daily. Dec. 18th.—The pruritus now was not incessant; the patient slept through a considerable part of the night; the red colour of the skin had faded, and the boundary of the parts immediately affected was less conspicuous: whey was substituted for the nitric acid drink on the 22d. He also took a small quantity of magnesia, his bowels being slightly constipated. On the 27th, Martin was bled for the third time, and with great relief to all the symptoms; the disease, indeed, now got rapidly well. The baths were continued, the vinegar wash renewed without injury, the diseased skin in various places began to assume its natural colour, and the limits between the healthy and affected surfaces were no longer visible along the upper parts of the thighs; the itching also became slight and transient. In getting well the eruption followed a course the reverse of that of its development, disappearing first from those places that had last become affected. During the fifty-three days he was under treatment, the patient took forty-six simple and six vapour baths. The nitric acid drink was continued for twenty-nine days, to the extent at least of three pints daily; it was then replaced by the whey which seemed to produce better effects. The venesections, especially the last, were beneficial; the application of the hog's lard was of no service, the vapour bath proved evidently too stimulating; lastly, the vinegar lotions gave great relief.

## STROPHULUS.

Vocab. Tooth-rash, *Strophulus*, Gum [*Red-gum*].

637. *Strophulus* is a cutaneous eruption which frequently occurs in children at the breast, characterized by red or white itchy papulæ of various sizes, evolved in succession, most commonly on the face and lower limbs, occasionally vanishing and recurring in an intermittent manner, and ending in resolution or furfuraceous desquamation.

638. *Causes*.—*Strophulus* commonly makes its appearance during the earlier months of infancy, and also in the course of cutting the first set of teeth. The disease seems occasionally to be traceable to the irritation of rough woolen clothing, the exposure of the body to too great a degree of warmth, and want of due attention to cleanliness. In the majority of cases, however, *strophulus* is evidently either preceded or accompanied by some gastro-intestinal disturbance, induced by cramming the child with too great a quantity of food, or with food of improper quality, to the irritation of teething, &c.

639. *Symptoms*.—The papulæ of *strophulus*, in their dimensions, colour, number and arrangement, present various shades of difference, from which the eruption acquires a considerable diversity of appear-

ance in different cases. These have been indicated by Willan by particular titles.

1st. The papulæ are sometimes of a vivid red, prominent, scattered over the cheeks, forearms, and dorsal aspect of the hands, and intermingled with erythematous patches of varying extent—*strophulus intertinctus* [red-gum]. These papulæ and red patches occasionally continue for several days, without the health of the infant appearing to suffer in any way; they occasionally vanish in the morning to reappear in the evening. Lastly, when the eruption is permanent, it begins to fade within a week or two, when the surface of the parts affected looks of a pale yellow colour, and becomes covered with a furfuraceous desquamation.

2d. Sometimes, on the contrary, the papulæ are small and white—*strophulus albidus* of Willan—and now and then appear surrounded by a slight blush; they then most usually occur on the face, neck, and breast, and are in general more prominent than those of the preceding variety.

3d. Lastly, the white papulæ of *strophulus* may appear with larger dimensions than those that have just been mentioned, and without any surrounding redness of their base—*strophulus candidus*, Willan. Their surface is smooth, shining, and of a duller white than the skin in their vicinity. These large papulæ are commonly scattered at great distance from one another over the loins, shoulders, and upper parts of the arms.

640. Besides these differences in point of size and colour, the papulæ of *strophulus* present yet two particular dispositions:

1st. The eruption may be very thick upon the face, trunk and extremities—*strophulus confertus*, Willan. On the face, the papulæ in this variety are smaller and more confluent than in the *strophulus intertinctus*; their colour is not so bright, and they are more generally prominent; they end within a week or two in a furfuraceous desquamation. On the trunk the eruption appears especially on the back and loins; there the papulæ are larger and less closely crowded together than on the face. If they be punctured deeply with a needle, a globule of transparent serous fluid may occasionally be squeezed out of them; this fluid is not deposited under the epidermis as in the vesicular eruptions, and is re-absorbed during the progress of the disease. On the upper extremities, as also on the neck and shoulders, the papulæ usually form irregular clusters; they end in a furfuraceous desquamation, and the skin in the affected parts continues for some time of a yellowish-gray colour. The papulæ evolved on the lower extremities always give rise to pruritus of a very violent description. They appear especially upon the calves of the legs, the thighs, buttocks and loins, in successive eruptions, which occasionally recur during several months.

2d. The papulæ of *strophulus*, finally, may appear on different regions of the skin in small circular clusters—*strophulus volaticus*, Willan. In each of these groups the number of papulæ usually varies from six to ten; they, as well as the interstices, are of a vivid red. After continuing four or five days, they begin to shrivel, grow sallow-looking, and finally end in a furfuraceous desquamation. The groups appear in succession on the face, trunk, and extremities. The eruption, which is very similar to the lichen *circumscriptus* of adults, may continue for several weeks.

641. These varieties of *strophulus* are often observed affecting the same child at one time. The white papulæ of the *strophulus albidus* are frequently seen mingled with the red papulæ of *strophulus intertinctus*; lastly, the papulæ may be crowded and confluent in several places, constituting *strophulus confertus*, whilst in others the voluminous and thinly scattered elevations of *strophulus candidus* are observed to prevail.

642. Whatever the form assumed by the eruption, *strophulus* is always accompanied with severe itching, a symptom which, as it is increased by the warmth of bed, is frequently productive of insomnia. Various symptoms produced by gastro-intestinal irritation, or the process of teething, are frequently associated with those characteristic of *strophulus*.

643. *Diagnosis*.—The papulæ of *strophulus* are always either whiter or redder than the healthy skin that surrounds them; those of prurigo, when they are intact, are nearly of the same colour as the integuments. Further, each of the successive eruptions of which

strophulus consists, has the course of an acute disease; prurigo approaches chronic disorders more nearly in its characters.

It is difficult, on the other hand, to establish satisfactory distinctions between strophulus and acute lichen. The shades of difference observed in these two diseases are ascribable to the differences in the age of the individual affected. The papulæ of acute lichen may, in fact, have the red colour, and appear either scattered or collected into groups, like those of strophulus. The latter malady, however, is more frequently marked by periodical intermissions and exacerbations, and is more intimately connected with the process of dentition than lichen. Further, the pale grayish-yellow tint that occasionally succeeds the disappearance of the papulæ of strophulus, is not nearly of such long continuance as that regularly observed to follow lichen, in which, indeed, the colour is often of the most decided coppery-yellow. To conclude, strophulus is never seen terminating by excoriations similar to those that follow lichen *agrius*.

*Strophulus confertus* is distinguished from *papular erythema* by the greater size of the patches in the latter, and their being attended with but little pruritus.

644. *Prognosis*.—Strophulus in itself is a disease of no gravity. When it appears associated with gastro-intestinal inflammatory affections, it is to these that the attention is to be particularly directed. These two diseases frequently alternate during the whole progress of the process of dentition, and the functional disturbance of the alimentary organs is often seen to abate with the evolution of the papulæ of strophulus.

The papulæ of strophulus vary in the period of their duration, from one of a few hours to one of several days; that of the eruption may extend over several weeks, according as the action of the causes which have produced it is intermittent and transient, or permanent.

645. *Treatment*.—When strophulus, in an infant otherwise healthy, appears to have been evolved under the influence of causes acting directly on the skin, the first indication naturally is to remove these or make them unavailing.

The pruritus may be appeased for an instant by dabbing the papulæ with cold salt and water, or vinegar and water. But when strophulus is symptomatic of inflammation of the digestive organs, or exists at the same time with such a disease, it is of primary importance to endeavour to subdue this internal affection by dietetic means adapted to the state of the digestive organs, by giving up all food save such as is supplied by the mother or nurse, and even by substituting sugar water in part for this, when febrile symptoms make their appearance; lastly, in diminishing the irritation of the external surface by the daily administration of baths of the decoction of bran or althea root, at a moderate temperature.

646. The cold bath lessens materially, and occasionally even cuts short almost at once, the papular inflammation of strophulus; but it is apt to increase the phlegmasiæ of the digestive organs which so frequently complicate the disease when it occurs during the process of teething.

Purgatives employed under similar circumstances are most generally detrimental. They occasionally produce vomiting and obstinate diarrhœa. It is also well as a general rule to abstain from the emetics and tonics recommended in strophulus by Willan, on account of the gastro-intestinal affections that so commonly occur along with the disease, and in which medicines of the classes mentioned are rarely admissible. (a)

#### *Historical Notices and particular Cases.*

647. Strophulus is even better known to mothers and nurses than to the physician. Those authors who have treated particularly of the diseases of infancy, have only spoken generally and vaguely of the eruption, under the name of *tooth-rash*, *red-gum*, &c., frequently showing, by the names adopted, that it was held especially to depend on the irritation of teething, or on some affection of the alimentary canal.

(a) The objection to purgatives in strophulus can only apply to those of an irritating nature; laxatives, such as rhubarb and magnesia, epsom salts in small doses, and castor oil will be generally found serviceable.

Lorry<sup>1</sup> regarded strophulus as a variety of lichen. Russel<sup>2</sup> evidently indicated the strophulus *intertinctus* under the title of *red-gum*. Sauvages<sup>3</sup> describes another variety—the strophulus *volaticus*, under the name of *feu volage*. Willan<sup>4</sup> was the first who gave a truly good description of the disease. (a)

The different appearances which strophulus may assume in a particular case, are readily assimilated to one or other of the varieties of the disease described by Willan. The following case will prove that if it be important to study the whole of the various forms assumed by this eruption, in order to render the account of it more complete and striking, it is of no less importance to avoid isolating them too much from each other, seeing that each may show itself in succession one after another in the same child during an interval of time more or less considerable.

CASE CIV. *Various forms of strophulus*.—A lady two months after her confinement, having been exposed to great fatigue of body and much anxiety of mind, seemed to lose the quality of excellent nurse, which she had hitherto proved herself; her child became restless during the night, crying incessantly, &c., and soon showed symptoms of gastro-intestinal derangement, combined with a papular eruption of strophulus upon the skin. This two-fold inflammation was treated by the daily use of the temperate bath; the mother also took a few temperate baths; her usual diet was not altered, this being habitually very regular, and she soon regained her strength; the child too thrived once more, but the strophulus continued for between four and five months, disappearing and recurring at uncertain intervals; now in the shape of red and inflamed papulæ upon the face and arms (strophulus *confertus* or strophulus *intertinctus*), and again under that of white and prominent papulæ (strophulus *albidus* and strophulus *candidus*), which were usually evolved upon the loins, buttocks and thighs. This papular inflammation was habitually increased during the night. The pruritus frequently awoke and prevented the child from sleeping. The application of cold water or a little saliva to the papulæ always seemed to appease the itchiness. For a long time the child had nothing but its mother's milk, upon which it thrived again. The symptoms of the gastro-intestinal inflammation disappeared with those of the affection of the skin. At the period of teething, the strophulus recurred afresh, but without any marked derangement of the digestive organs. At the age of two years the infant became affected with laryngitis, and six months later with bronchitis, from both of which attacks, actively treated by the application of leeches, it recovered completely.

#### PRURIGO.

Vocab. *Cnesmos, Prurigo, Pruritus, Scabies Papuliformis.*

648. Prurigo is characterized by an eruption of papulæ, nearly of the same colour as the skin, and accompanied with pruritus of the most intense description. The papulæ, larger than those of lichen, after having been torn by the nails, are usually replaced by small black and circular scabs; it happens more rarely that in decaying naturally they leave minute yellowish stains behind them upon the skin.

649. Prurigo is usually evolved either at once or successively upon several regions of the body; it is very seldom, indeed, that it attacks no more than one.

650. Prurigo presents three principal varieties:

1st. The eruption in one case is proclaimed by a troublesome feeling of itchiness over the shoulders, upper part of the breast, lumbar region, outer surfaces of the arms and thighs, &c. When the parts so affected are examined with care, numbers of papulæ are perceived, soft to the touch, and broader than those of lichen, from which they
